The star-like appearance of astrovirus noted by Madeley and Cosgrove is due to spikes studded on the virion surface. Within the past decade, extensive progress has been made in our knowledge of the capsid's structure using methods including electron and cryo-electron microscopy, X-ray crystallography, and density ultracentrifugation. The crystal structures for the HAstV8 spike, HAstV1 full capsid, HAstV2 spike, and turkey astrovirus type 2 spike have all been described. These studies demonstrate that astrovirus particles are approximately 43 nm in diameter with $T = 3$ icosahedral symmetry (Fig. 2A) and closely resemble the structure of the human hepatitis E virus virion.

The capsid protein is translated as an inactive VP90 precursor that undergoes cleavage before assembly into an infectious virion. First, intracellular caspases cleave VP90 to generate VP70, of which 180 copies are needed to form an immature virion. Two separate studies reported that this caspase cleavage is necessary for viral particles to be released from the cell. Once released from the cell, extracellular proteases further cleave VP70 of the immature virions into VP34, VP27, and VP25 to form mature virions. VP34 makes up the continuous inner core while VP27/VP25 form the spike domains (Fig. 2A). The immature virion has an estimated 90 spikes which is reduced to just 30 spikes on an infectious particle following this final cleavage. Through antigenic studies, these spikes are thought to contain the binding site to the yet to be identified host cell receptor.

The astrovirus capsid appears to have other functional roles although its full role in the replication cycle remains an area of active research. The capsid has been reported to bind both complement 1q and mannose-binding lectin to inhibit the classical and lectin pathways of complement. This could be a clue as to how astrovirus is able to infect without causing noticeable histological changes. The astrovirus capsid has also been shown to act as a novel enterotoxin in vitro and in vivo.

Genome

The astrovirus genome is a single-stranded positive-sense RNA segment of approximately 6.2–7.7 kb. The genetic material contains both 5' and 3' untranslated regions and three open reading frames (ORFs) flanked by 5' viral genome-linked protein (VPg) and a 3' poly(A) tail.

Fig. 2 Astrovirus Genome and Virion Structure. (A) $T = 3$ icosahedral structure of the astrovirus capsid composed by an inner core of VP34 and VP27/VP25 in the spike domains. (B) The three open reading frames (ORF) of astrovirus flanked by a 5' viral genome linked protein (VPg) and a 3' poly(A) tail with known protein coding regions designated by inset boxes. Darker regions of ORF2 indicate hypervariable regions. Modified from SIB Swiss Institute of Bioinformatics, ViralZone Astroviridae.

poly(A) tail (Fig. 2B). ORF1a and ORF1b, located at the 5' end of the genome, both encode the astrovirus nonstructural proteins. While astrovirus could have as many as five nonstructural proteins, the three characterized nonstructural proteins include a serine protease, the VPg, and an RNA-dependent RNA polymerase (RdRp). A ribosomal frameshift signal is present between ORF1a and ORF1b and is critical for the correct translation of the RdRp. ORF2, at the 5' end of the genome, encodes the astrovirus structural protein and is expressed from a subgenomic RNA (sgRNA). This sgRNA was confirmed when two species of viral RNA were detected in astrovirus infected cells, both full-length genomic RNA and a roughly 2.8 kb sgRNA. This allows for an excess of astrovirus capsid protein to be translated and ready for assembly during the viral replication cycle.

Life Cycle

Binding and Entry

Despite dedicated work, much of the astrovirus replication cycle remains unknown. Our understanding comes mainly from studying a few of the classical HAsTV genotypes, and inference from the replication cycles of closely related viral families like *Togaviridae* and *Caliciviridae*. The cellular receptor or receptors for astroviruses are still unknown, and given that different cell types have different susceptibilities for various HAsTV genotypes it is likely a variety of binding factors may be needed for cell entry. For example, while human colorectal adenocarcinoma (Caco-2) cells can support the replication of all HAsTV1–8 genotypes, baby hamster kidney (BHK-21) cells can only be infected by HAsTV2, and human colorectal carcinoma epithelial (HTC-15) cells can support only HAsTV1 replication. Crystallization of the capsid and spike proteins revealed conserved polysaccharide binding motifs meaning these could be involved in viral binding. Nevertheless, pretreatment of Caco-2 cells with heparinase was unable to inhibit viral binding, while pretreatment with chondroitinase was only able to reduce infectivity, showing further research is needed to understand how these sites could be involved in binding.

After attachment of the virus to the host cell, entry appears to be facilitated by clathrin-mediated endocytosis. Electron microscopy has displayed astrovirus particles localized in coated pits and vesicles and blocking clathrin assembly has been shown to inhibit HAsTV8 replication. Once endocytosed, vesicles containing astrovirus particles must reach late endosomes. Blocking Rab7 was shown to block replication of HAsTV8 suggesting the acidic environment found in late endosomes is required for proper uncoating and release of the viral genome.

Uncoating and Replication

While the exact mechanism for viral uncoating is unknown, studies show the process is membrane associated and mediated by an endoplasmic reticulum signal motif located in the C-terminus of VP90. Analysis of recombinant viral-like particles (VLPs) showed that divalent cations in the capsid protein provide stability to the viral particles. Therefore, the acidic environment of late endosomes and typically low cation concentration in the cytoplasm should both promote virus uncoating.

Once the viral genome has been released, the first proteins translated after viral uncoating are the nonstructural proteins encoded by ORF1a and ORF1b. The nonstructural polyprotein, nsp1a, is cleaved by the viral serine protease, conceivably along with unidentified cellular proteases into smaller proteins some whose function is still unknown. One of the nsp1a proteins, nsp1a/4, is a VPg that has been shown to localize with viral RNA and is thought to facilitate viral replication and possibly transcription from the negative-sense RNA template. Although direct interaction between the VPg and viral genome has not been confirmed, pretreatment of viral RNA with proteinase K before transfection into permissive cells significantly reduced the infectious virus produced, indicating a protein moiety is required for successful replication. The production of the capsid protein involves both genomic and sgRNA, with an excess of sgRNA at 12 h post-infection (hpi) coinciding with higher levels of capsid protein production. This is characteristic common among many positive-sense single-stranded RNA viruses as a means of evading repression of translation by the host. While caliciviruses possess a VPg on their sgRNA segments to initiate its translation, it is unclear if astroviruses utilize a similar mechanism.

The precise role host proteins play during astrovirus replication has yet to be fully addressed, although one study has implicated host proteins involved in fatty acid and cholesterol synthesis, phosphatidylinositol and inositol metabolism, and RNA helicase activity, all being necessary viral replication. Our lab has demonstrated that the increase in phosphorylated ERK1/2 protein that occurs within 15 min after viral binding is required for successful viral replication. Recently, others have reported the ubiquitin proteasome system is also needed replication of the viral genome and sgRNA.

Assembly and Release

The location for viral assembly appears to be genotype dependent with HAsTV4 and HAsTV8 accumulating in double membrane vacuoles near the nucleus, while ovine astrovirus has been found in lysosomes and autophagic vesicles. In these membraned sites, viral capsids can self-assemble into full virions or VLPs, and viral release occurs via an unknown, nonlytic mechanism without significant cell death. It has been hypothesized that astrovirus release could occur through similar nonlytic mechanisms used by rotavirus or poliovirus, or through a form of cell membrane destabilization. Overall, many questions remain involving the replication cycle of astrovirus and more research is needed to elucidate key aspects of every step in the cycle including what

receptors and binding factors are used, the mechanism of viral release without inducing cell death, and how cellular factors are involved in this process.

Epidemiology

Astrovirus is spread via the fecal-oral route and can be transmitted through contaminated food and water, human-to-human, or through nosocomial infection. The fecal-oral route of transmission was confirmed through two volunteer studies, where after ingesting astrovirus subjects developed symptoms and detectable serological responses.

Classical HAsTV

Classical HAsTV infections are predominantly reported in pediatric population, but the elderly and immunocompromised are also susceptible to infection. Although less common, healthy adults have been reported with HAsTV infections. The age range of typical infection is newborn to 5 years, with up to 90% of children ages 5 years and up having detectable serum antibodies. Although there tends to be a seasonal pattern with higher incidence in winter, possibly due to enhanced stability in colder temperatures, astrovirus circulates year-round with infections reported in summer months as well.

Classical HAsTVs are thought to be responsible for between 2% and 9% of all acute, non-bacterial diarrhea in children. Reported in 2013, the mean incidence of HAsTV infection was 11% worldwide, with 7% incidence in rural areas and 23% in urban areas. The incidence of infection tends to be higher in developing countries, most likely due to poor hygiene and water treatment practices. Astrovirus infection statistics are greatly hindered by underreporting and asymptomatic infections. However, the development of more sensitive real-time RT-PCR have enabled significantly higher rates of HAsTV infections in asymptomatic children to be detected. With these new screening methods, the rate of HAsTV positive samples from asymptomatic children is thought to be roughly 4%. Of the classical genotypes, HAsTV1 is the most frequently isolated worldwide, with the exception of Mexico where HAsTV2 dominates. The incidence of HAsTV infection has been decreasing over the past three decades from 22% in the 1980s to just 5% in the 2000s. This could be due to novel HAsTVs outcompeting the classical genotypes, since reports have shown their prevalence is rising.

Novel HAsTV

The association between the MLB and VA clades of HAsTV and clinical disease is still somewhat ambiguous compared to the classical genotypes, which makes accurate reporting difficult. Published reports have exhibited this in the large variation in prevalence from one geographic location to another. One review of novel HAsTV prevalence, describes an overall positivity rate from stool samples 1.5% lower than that observed for classic HAsTVs. However, one study from Japan in 2016 found more MLB-HAsTV positive samples, 10.6%, than classic HAsTVs, 5.1%. Although most case reports exhibit a generally low prevalence of novel HAsTVs, studies have revealed the seroprevalence of HAsTV-MLB1 to be 86% and HAsTV-VA1 to be 65% indicating a large portion of the population have seen these viruses previously. In a study of immunocompromised pediatric oncology patients, half of the samples were positive for HAsTV1, however HAsTV-VA2 and HAsTV-MLB1 were also present in 21% and 13% of samples, respectively. The authors of this study did comment that the PCR screening method used was unable to detect other members of the HAsTV-VA and HAsTV-MLB clades, so these genotypes may have been more prevalent than reported.

Clinical Features

Human Disease

The typical symptom of HAsTV infection is watery diarrhea that lasts 2–4 days and can be less commonly accompanied by fever, headaches, abdominal pain and anorexia. Not all HAsTV infections present with symptoms, since many infections in healthy individuals tend to be asymptomatic, which could be due to previous exposure to the virus conferring immunity.

In the immunocompromised population, HAsTV infections are of increased interest due to recent reports of severe symptoms and extra-gastrointestinal dissemination. First reported in 2010, a case report involving a 15-year old boy with X-linked agammaglobulinaemia suggested HAsTV to be the causative agent in encephalitis and meningitis. While virus specific primers were unable to detect the virus, next-generation sequencing (NGS) identified the presence of HAsTV in the patient's biopsy samples. Since then, eight additional cases have linked encephalitis and meningitis to HAsTV infection in predominately immunocompromised patients, though one case was in an otherwise healthy individual. In eight out of the nine cases, a non-classical genotype was identified in patient samples. These studies suggest that astroviruses have the potential to cause systemic infection, highlighting the need to research astrovirus pathogenesis with both classical and non-classical genotypes. Especially when epidemiological studies have shown infections caused by non-canonical viruses are becoming less rare.

Animal Disease

As in humans, diarrhea is the main symptom of astrovirus infection in many animal species including turkeys, chicken, cattle, lambs, piglets, and deer, among others, although cases of asymptomatic infections in animals have been reported. Chicken astrovirus infection has been associated with two different conditions in chicken hatchlings, runting-stunting syndrome and “white chick” syndrome. These syndromes are characterized by decreased hatch-rate, poor weight gain, increased chick mortality and weakness. It can lead to pale plumage in chickens where “white chick” syndrome gets its name. Likewise, astrovirus infections in turkeys also causes stunted growth associated with poult enteritis mortality syndrome (PEMS). PEMS affects newly hatched turkey poults and is characterized by diarrhea, dehydration, and increased mortality. Along with diarrhea associated disease in animals, there have been cases of astrovirus-associated encephalitis and meningitis in mink and cows. Recently, porcine astrovirus type 3 was detected in central nervous system tissues from pigs suffering a neurologic disorder characterized by hind limb weakness to quadriplegia and occasionally convulsions. With improved screening, detection and sequencing techniques, we are now able to detect the variety of symptoms associated with astrovirus infection, however further research is still needed to discover how the virus is causing disease.

Pathogenesis

Obstacles

Several obstacles must be overcome in order to uncover the mechanisms of astrovirus pathogenesis. To date, researchers make do without proper cell culture methods for all astrovirus genotypes or a well-characterized or clinically relevant small animal model. Caco-2 cells are the most common cell culture model for *in vitro* studies on classical HAsV genotypes. However, this is an immortalized cancerous cell line that may not completely mimic the same mechanisms occurring *in vivo*. Furthermore, cell culture systems for the MLB and VA genotypes are limited or non-existent, which greatly limits our ability to study these novel genotypes.

Modeling astrovirus disease *in vivo* has also been challenging. The turkey poult model has historically been the most widely used animal model in astrovirus research. Although poults develop clinical symptoms upon infection with turkey astrovirus type-2 (TAsV2), this virus is an Avastrovirus and genetically distinct from Mamastroviruses. It is still unclear if characteristics of disease resulting from Avastrovirus infection translate to classical or non-classical HAsV infection. Studies using turkey poults are also burdened by the lack of a cell culture system in which to grow virus; researchers are restricted to generating the virus in embryonated turkey eggs. Furthermore, planning experiments is difficult due to a low hatch rate, approximately 50%, decreasing overall sample sizes, and the highly transmissible nature of astrovirus requiring uninfected controls to be housed separately to avoid cross-contamination. Most importantly, turkey-specific antibodies and reagents are rarely commercially available, which greatly reduces which technical methods can be utilized.

In 2012, four murine astroviruses (MuAsV, STL1 – STL4) were identified in mice housed at Washington University in St. Louis, MO. This discovery offered the potential to develop a traditional small animal model to study astrovirus. Unlike TAsV-infected turkey poults, MuAsV-infected mice do not exhibit diarrhea yet exhibit low level persistence and viral shedding for long periods of time. MuAsV has also been identified in mice purchased from multiple vendors, making obtaining mice without underlying astrovirus infection challenging. The characterization of the MuAsV infection is ongoing, but researchers are hopeful this model holds the key many future discoveries. Nevertheless, using the resources available, researchers are expanding the body of knowledge on astrovirus pathogenesis (summarized in [Fig. 3](#)).

Mechanism of Disease

To date, most pathogenesis studies have focused on understanding the mechanism by which astrovirus induces diarrhea. Reports have shown astrovirus infection in turkey poults results in relocalization of the sodium transport proteins NHE3 and SGLT-1 from the cell membrane into the cytoplasm of intestinal epithelial cells, supporting a hypothesis that astrovirus disrupts ionic transport causing sodium malabsorption and osmotic diarrhea. Other intestinal pathogens disrupt the intestinal epithelium by causing inflammation and cell death. However, astrovirus-induced diarrhea occurs without triggering cell death or inflammation, although there is one report of HAsV8 inducing apoptosis in Caco-2 cells. Instead HAsV causes barrier permeability by disrupting intestinal cellular junctions. Tight junctions are highly regulated cell-cell associations that maintain cell polarity and regulate the passage of nutrients, other solutes and microorganisms from the intestinal lumen across the epithelium. Cellular junctions are comprised of the tight junction complex, which includes proteins such as occludin, claudin, ZO-1, and cadherins. Loss of tight junctions can result in increasing fluid in the lumen of the intestine and diarrhea.

Multiple studies report that AsV infection alters permeability of the intestinal barrier caused by redistribution of junctional proteins. *In vitro*, HAsV infection caused a drop in transepithelial resistance (TER) in Caco-2 monolayers and allowed for greater flux of FITC–dextran across the cell monolayer. The decrease in TER and increase in flux began between 16 and 20 hpi, with maximum permeability achieved by 36 and 48 hpi. HAsV1 has been shown to increase intestinal barrier permeability *in vitro*, possibly due to a reduction in actin fibers, reduction of occludin from the junctional complex and loss of E-cadherin by 24 hpi. Studies in the turkey poult yielded comparable results, where infected poults had increased luminal-to-serosal flux and disruption

Fig. 3 Astrovirus increases barrier permeability in the gut epithelium. (A) Normal intestinal epithelial cells maintain tightly regulated barrier permeability. (B) In infected cells, intestinal epithelial cells upregulate iNOS inducing macrophages to secrete NO, and TGF- β within the epithelial cells is activated. IFN- β is induced in an effort to control infection. Tight junction proteins and the sodium transporters are relocalized, leading to the breakdown of barrier permeability allowing exchange of ions and solutes across the intestinal epithelium.

of F-actin. There is evidence that MuAstV infection also increased intestinal permeability, as indicated by orally administered FITC-dextran crossing the intestinal epithelium reaching the blood.

Remarkably, astrovirus-induced disruption of barrier integrity was found to be independent of active replication. Reports by Moser *et al.* found both UV-inactivated HAsTV and recombinant capsid protein could decrease barrier permeability in Caco-2 cells as well as activate ERK1/2. In vivo, administration of the recombinant TAsTV2 capsid protein induced acute diarrhea, and capsid inoculated animals experienced relocalization of SGLT-1 from the plasma membrane, comparable to those infected with virus.

Immune Response

The immune response to astrovirus is not well-characterized, but studies suggest that infection does not produce overt inflammation. It is assumed that the innate immune system plays a vital role in controlling the virus because the course of infection with astrovirus is relatively short. One essential arm of the innate immune system is the interferon response. Astrovirus replication was found to be impacted by the type I interferon (IFN) response. Two reports have shown IFN- β levels increase after HAsTV infection and the addition of exogenous IFN- β can protect epithelial barrier integrity. Contrasting the induction of barrier permeability, productive replication is required to induce IFN- β in vitro. In vivo, IFNAR knockout mice, which lack the IFN- α receptor making them unable to respond to type I IFNs, could not clear an astrovirus infection unlike wild-type mice.

Along with inhibiting complement factors, astrovirus may be modulating the immune response by activating the immunosuppressive cytokine, TGF- β . Infected turkey poults exhibited increased levels of active TGF- β to up 12 days after infection. Astrovirus has been shown to not only infect intestinal epithelial cells but also intestinal macrophages, although infection in macrophages led to abortive replication. While astrovirus infection results in decreased macrophage function and viability, infected macrophages produce more nitrogen oxide (NO) because of increased inducible NO synthase (iNOS) produced by infected epithelial cells. The NO produced by macrophages has been reported to then inhibit astrovirus replication in turkey poults.

The innate immune response controls the initial spread of astrovirus and enables the host to mount an effective humoral and cell-mediated adaptive response. Nearly 70% of healthy adults have detectable antibodies against astroviruses. Studies in human volunteers have shown a direct link between having anti-astrovirus antibodies and disease, where subjects without antibodies to the virus had more severe symptoms. Further reports have shown individuals can develop anti-astrovirus antibodies without the presence of symptoms as is the case with poultry abattoir workers with antibodies against TAsTV. This finding was contrary to the widely held belief that astrovirus infections were species-specific, and provided evidence supporting the possibility for zoonotic transmission. However, further work is needed in this area of investigation.

Recently, antibodies that neutralized viral infectivity have been discovered. Bogdanoff *et al.* have mapped the neutralizing epitopes of HAstV2 demonstrating only antibodies to spike protein, not the core, can prevent binding to Caco-2 cells. Additional analysis of several genotype specific neutralizing antibodies determined a quaternary epitope on each side of the dimeric capsid spike necessary for neutralization. These studies could help determine components for future vaccines to induce the production of cross-protective neutralizing antibodies against astrovirus.

In terms of cell-mediated adaptive response, astrovirus specific T cells are also thought to play a significant role in viral clearance. A challenge of biopsy specimens from the small intestine of healthy adults with inactivated HAstV demonstrated HAstV-specific CD4⁺ and CD8⁺ T cells reside in these tissues and could prevent reinfection. Recent work in the mouse model has shown Rag1 knockout mice, which lack B and T cells, shed more virus in their feces than wild-type mice. This study also detected higher viral replication in intestinal tissues, mesenteric lymph nodes, spleen, liver, and kidneys of Rag1 knockout mice, indicating B and T cells are necessary in preventing systemic spread of astrovirus.

Diagnosis

Initially, HAstV was detected via electron microscopy. However, using electron microscopy is time consuming and is impractical for high-throughput screening purposes. In 1995, the first conventional RT-PCR and enzyme immunoassays were developed to determine the antigenic groups of HAstV. Several real-time RT-PCR methods have now been developed for quick screening of HAstV, including many that are multiplexed to detect additional enteric viruses. However, these methods do not detect non-classical HAstV VA or MLB genotypes. To date, there is only one real-time RT-PCR multiplex method accurately detects classical HAstV1–8, MLB1, and VA2. Developing more comprehensive real-time RT-PCR methods to detect the 16 known genotypes has been hindered by limited sequence information available through public databases. Adding to the sequences available and validating new detection methods is essential for researchers to better delineate astrovirus epidemiology and relationship to disease.

Treatment

Currently, there are no vaccine or medical treatment options for HAstV. This is in part due to the short duration and relatively mild symptoms that HAstV infection causes. The low interest in developing a HAstV vaccine could be because of its believed low clinical impact or the need for a multivalent vaccine to cover multiple genotypes. Although most infections resolve without intervention, if treatment is necessary, it generally involves alleviating symptoms. HAstV-induced diarrhea has the potential to cause dehydration in infected individuals and therefore may require oral or intravenous fluid replacement. Since immunocompromised individuals could be at risk of astrovirus spreading systemically, it has been suggested intravenous IgG be used as treatment, although more studies are needed to determine the efficacy of such treatments.

Prevention

The best form of prevention is to stop the spread of the virus. In order to fully disinfect surfaces and contaminated fomites most healthcare facilities regularly use 90% ethanol, however this treatment was shown to be ineffective against astrovirus. Astrovirus is a remarkably hearty virus that can remain stable at low pH, is resistant to many detergents, and even lipid and chlorine solvents are incapable of inactivating the virus. However, reports have shown that formaldehyde and peroxymonosulfate can fully inactivate the virus. Temperature modulation also has very little effect since astrovirus is also very stable at low temperatures and can remain infectious for up to ten years.

Astrovirus has been detected in environmental water samples and shown to persist in drinking water, proving the importance of water treatment in preventing the spread of the virus. Typical water treatment involves chlorine disinfection with residual free chlorine in the range of 0.2–1 mg/L, and a maximum residual disinfectant level of 4mg/L allowed by the Environmental Protection Agency. Astrovirus infectivity has been shown to be decreased by 3 logs at the height of the typical range, 1mg/L free chlorine, for two hours. Most studies to date on disinfection and inactivation have focused on classical HAstV genotypes. While bleach use is recommended for the inactivation of novel HAstV genotypes, more research is necessary to determine exact protocols for their inactivation.

Classification

Avian hepadnaviruses belong to the avihepadnavirus genus of the hepadnaviridae family and are related phylogenetically to human hepatitis B virus (HBV) and other viruses of the orthohepadnavirus genus, which infect mammals. Avian hepadnaviruses are related phylogenetically to each other through similarities in genome sequence and organization of open reading frames (ORF). Only two species have been assigned within the avihepadnavirus genus: duck hepatitis B virus (DHBV), first isolated from Pekin ducks (*Anas domestica*), and heron hepatitis B virus (HHBV), isolated from grey herons (*Ardea cinerea*). HHBV was assigned as a species based both on genome divergence and a host range difference from DHBV. DHBV isolates have been found not only in domesticated ducks, but also in the puna teal (*Anas puna*), the Chiloe wigeon (*Anas sibilatrix*) and, in the wild, the mallard, the species from which Pekin ducks and most other domesticated ducks (except Muscovy) were derived.

Avian hepadnaviruses less closely related to DHBV but currently unassigned as distinct species have also been isolated. Viruses isolated from geese include the Ross' goose hepatitis virus (RGHV) from Ross' geese (*Anser rossii*) and Mandarin ducks (*Aix galericulata*), the snow goose hepatitis B virus (SGHBV) from snow geese (*Anser caerulescens*) and the sheldgoose hepatitis B virus from the ashy-headed sheldgoose (ASHBV) (*Chloephaga poliocephala*) and Orinoco sheldgoose (OSHBV) (*Neochen jubata*). The crane hepatitis B virus (CCHBV) has been isolated from demoiselle cranes (*Anthropoides virgo*) and grey crowned cranes (*Balearica regulorum*). Parrot hepatitis B virus (PHBV) has been isolated from ring-necked parakeets (*Psittacula krameri*), an African grey parrot (*Psittacus erithacus*), an Alexandrine Parakeet (*Psittacula eupatria*) and a crimson rosella (*Platycercus elegans*). The stork hepatitis B virus (STHBV) has been isolated from white storks (*Ciconia ciconia*) and the elegant-crested tinamou hepatitis B virus (ETHBV) has been isolated from elegant-crested tinamou (*Eudromia elegans*) (Fig. 1(A); Table 1A).

Virus Structure

Avian hepadnaviruses are enveloped viruses possessing an icosahedral nucleocapsid and ~3000 nt relaxed circular double-stranded DNA (rcDNA) genome (Fig. 2). DHBV, the prototypic avian hepadnavirus, has a diameter of 40–45 nm. The envelope of DHBV is composed of a lipid bilayer containing 2 transmembrane DHBV surface antigen (DHBsAg) proteins, PreS/S and S (36 and 17 kDa respectively). These two proteins are synthesized from the same ORF, with initiation of PreS/S occurring upstream of S and share a common carboxy-terminus. An additional ~28 kDa DHBsAg protein has been detected in DHBV-infected liver but it is unclear if this is a degradation product of PreS/S or is translated from an AUG codon mapping between the start sites of PreS/S and S. The envelope proteins, PreS/S and S, participate in virion formation and also self-assemble into non-infectious DHBsAg particles. DHBsAg assembles in the endoplasmic reticulum and is released from infected hepatocytes in a 500–1000-fold excess over infectious virions. DHBsAg particles do not contain a virus nucleocapsid or viral nucleic acids and are pleomorphic and spherical, with a diameter of ~35–60 nm. Many are almost indistinguishable from DHBV virions by electron microscopy (EM).

The nucleocapsid of DHBV is icosahedral, as observed by cryo-EM, has a diameter of ~38 nm and is composed of 90 or 120 subunits arranged in T = 3 or T = 4 symmetry. The subunits are dimers of the 30 kDa non-glycosylated DHBV core antigen (DHBcAg) protein, or C protein. The rcDNA genome, virus encoded polymerase and cellular chaperones are contained in the nucleocapsid. The DHBV polymerase is a 90 kDa protein that functions as an RNA-dependent DNA polymerase and a DNA-

Fig. 1 Phylogenetic relationships of exogenous avian hepadnaviruses and endogenous avian hepadnavirus elements. (A). Phylogenetic analysis of full-length exogenous avian hepadnavirus genomes (Table 1A) was performed using ClustalW sequence alignment with the ClustalW cost matrix, the Neighbor-Joining method with the HKY nucleotide model and 1000 bootstraps and is shown as an unrooted tree. Scale bar = 0.09 nucleotide substitutions per site. (B). Phylogenetic analysis of partial polymerase amino acid (AA) sequences of the endogenous avian hepadnavirus elements, eZHBV_C (HAS) (Hypothetical Ancestral Sequence described by Suh, A., Brosius, J., Schmitz, J., Kriegs, J.O., 2013. The genome of a mesozoic paleovirus reveals the evolution of hepatitis B viruses. *Nature Communications* 4, 1791; 778 AA), eHBV-1-BK008520.1 (679 AA), eHBV-2-BK008521.1 (592 AA) and eHBV-HQ116565.1 (195 AA) (Table 1B), compared to full-length polymerase AA sequences (785–793 AA) of selected exogenous avian hepadnaviruses (Table 1A). Analysis was performed using ClustalW sequence alignment with the BLOSUM cost matrix, Neighbor-Joining method with the Jukes-Cantor model and 1000 bootstrap replicates and is shown as an unrooted tree. Scale bar = 0.09 AA substitutions per site. The percentage of bootstrap replicates that supported each branch is shown in both A and B.

dependent DNA polymerase. The polymerase protein has 4 separate domains listed from the N-terminal end, including a terminal protein (TP), 'spacer', reverse transcriptase (RT) and RNase H domain.

Also released from hepatocytes and circulating in the bloodstream of infected ducks is DHBV e antigen (DHBeAg), which includes proteolytically processed forms of the PreC/C protein ranging in size from a non-glycosylated 27 kDa to ~30–33 kDa glycosylated forms. DHBeAg is thought to be similar in function to the better described HBV e antigen: based upon studies in HBV transgenic mice, HBV e antigen appears to suppress the host immune response to HBV. Thus, it is possible that DHBeAg performs a similar role, facilitating the development of chronic DHBV infections.

Genome

The avian hepadnaviruses have rcDNA genomes with similar genome organization to the orthohepadnaviruses, including the presence of overlapping ORFs all present on the negative strand (Fig. 2). The genomes of DHBV isolates range in size from 3021 to 3027 nt (Table 1A). The negative strand of rcDNA is nicked, with a 9 nt terminal redundancy (r) and with the virus polymerase covalently attached to its 5' end. Similarly, the positive strand of the DHBV genome has an 18 nt RNA primer attached to its 5' end and is incomplete in rcDNA genomes, with a minimum gap of 12 nt (Fig. 2); as illustrated below (Fig. 4), this gap is likely due to the inability of the polymerase to displace the positive strand RNA primer from DR2.

The negative strand of rcDNA contains a P ORF, PreS/S ORF and PreC/C ORF, encoding the polymerase, PreS/S and S proteins, and DHBeAg and DHBeAg proteins, respectively. The P ORF, read in a +1 frame, completely overlaps the PreS/S ORF, read in a

+ 2 frame, leading to out of frame overlap between the 'spacer' and RT domains of the polymerase and the PreS and S regions of the surface proteins respectively. The P ORF also overlaps out of frame with the downstream region of the C ORF, read in a + 3 frame, leading to overlap between the TP domain of the polymerase and the C-terminal domain of DHBcAg (Fig. 2). These overlaps place evolutionary constraints on the genome with single mutations potentially leading to changes in more than one ORF. The positive strand of rcDNA does not encode any functional ORFs.

The DHBV genome was originally thought to contain only 3 ORFs, and to lack an ORF encoding a protein analogous to the orthohepadnavirus X protein. This is surprising because the HBV X protein is required for transcription of HBV DNA, which is otherwise suppressed by a host-complex targeting episomal DNAs. It was subsequently discovered that DHBV has a fourth ORF, the X ORF, which lacks a conventional start codon but can be read in + 2 frame to direct synthesis of a candidate DHBV X protein. The significance of this

Fig. 2 DHBV genome organization. The rcDNA genome of AusDHBV (GenBank AJ006350) is shown at the top, with the virus polymerase covalently attached to the 5' end of the negative strand and an 18 nt RNA primer attached to the 5' end of the positive strand. The genome is numbered clockwise from a conserved EcoRI site at nt 3027/1 and contains 2 direct repeat (DR) sequences (DR1 and DR2, nt 2541–2552 and 2483–2494 respectively). The location of the P, PreS/S, PreC/C and X ORFs, pregenomic, L and S mRNAs and common polyadenylation site (nt 2778–2783) are also shown. None of the major mRNAs are spliced. Thus, each mRNA has its own promoter. Pregenomic RNA has a terminal redundancy (TR) of 243 nt and is the mRNA for both the DHBcAg and polymerase proteins from the C ORF and P ORF respectively. Pregenomic RNA lacks the AUG of the PreC/C ORF, and DHBcAg is synthesised instead from an mRNA a few nt longer at the 5' end than pregenomic RNA (not shown). The L and S mRNAs encode the DHBsAg proteins, PreS/S and S, respectively. The X ORF, which lacks a conventional start codon, is used to produce X mRNA (not shown) allowing synthesis of a candidate X protein (as described in the text). The more rarely synthesized double stranded-linear DNA (dsDNA) is shown at the bottom.

observation is still unclear. Knockout of the X gene of DHBV did not alter the time course of DHBV infection: the X gene deletion mutant spread rapidly through the liver of newly-hatched ducks and caused persistent infection. Interestingly, other avian hepadnaviruses including HHBV, STHBV, RGHV, ASHBV and OSHBV, all have an AUG codon near the beginning of the X ORF.

The difference in size between the genomes of the avian (e.g., DHBV, 3021–3027 nt) and the orthohepadnaviruses (e.g., HBV, 3200–3300 nt), is due in part to the absence of a 150 nt stretch in the S ORF of the avian virus. This region in the HBV genome encodes the 'a' determinant, a highly immuno-dominant region present in HBV surface antigen. Most neutralizing anti-HBV surface antigen antibodies are directed towards the 'a' determinant. Indeed, HBV strains with mutations in the 'a' determinant can establish infection and replicate in vaccinated hosts as vaccine escape mutants. The effect of the absence of an 'a' determinant in DHBV is unknown but both DHBV PreS/S and S proteins can induce high-titer neutralizing antibodies.

Life Cycle

Although the avian and orthohepadnaviruses share only 40% genome sequence homology, their life cycles and replication strategies are similar. In brief, their rcDNA genome is converted in the nucleus to covalently closed circular DNA (cccDNA), which is used as the transcriptional template for all the viral mRNAs, including the pregenome (Fig. 2). Pregenomic RNA, in addition to functioning as the mRNA for DHBcAg and polymerase, is encapsidated by DHBcAg and reverse transcribed, in the cytoplasm, into rcDNA and double stranded-linear DNA (dsDNA) (Fig. 3).

Fig. 3 DHBV infection of hepatocytes. Virions, shown at the top may have either an rcDNA or, more rarely, a dsDNA genome. Upon infection, virus nucleocapsids lose their envelope and move to the nucleus. Virus DNA is released from nucleocapsids and probably enters the nucleus at nuclear pores. Both rcDNA and dsDNA give rise to cccDNA, the virus transcriptional template. cccDNA is used by host cell RNA polymerase II to make all viral mRNAs including the pregenomic RNA that is reverse transcribed into rcDNA or dsDNA. The dsDNA form also has a propensity to integrate into host cell DNA. Early in infection, cccDNA copy number increases to 5–50 copies/cell by intracellular amplification, in which newly made rcDNA and dsDNA migrate to the nucleus rather than being exported as progeny virus; later, nucleocapsids containing rcDNA and dsDNA bud into the ER and are released as progeny virus.

Hepatocytes, the major parenchymal cell of the liver, are the primary site of DHBV infection. Hepatocyte specificity is determined by a cell surface receptor for virus binding and entry and by a viral preference for liver-enriched transcription factors. Receptor binding occurs via the PreS region of DHBsAg and is followed by receptor-mediated endocytosis. The cellular protein carboxypeptidase D (180 kDa) binds DHBsAg particles and DHBV with high affinity and is found on both internal and external membranes of the cell. An additional DHBV binding protein, glycine decarboxylase (120 kDa), has also been identified in liver, kidney and pancreas, all sites of DHBV infection. These 2 proteins are potential components of a DHBV receptor complex but definitive proof that they mediate virus infection is still lacking. In contrast, the receptor used by HBV was recently identified as the human sodium taurocholate co-transporting polypeptide (hNTCP). hNTCP, a multiple transmembrane transporter predominantly expressed in the liver, binds the N-terminal region of the HBV large surface protein, leading to viral entry via receptor-mediated endocytosis.

The immediate sequel to DHBV uptake is transport of rcDNA to the nucleus (**Fig. 3**). Following transport, the covalently linked polymerase protein, the RNA primer and the 9 nt terminal redundancy in the negative strand are removed, the positive strand is completed, and ligation of the ends of each DNA strand takes place to form cccDNA. Once formed, cccDNA is transcribed by host RNA polymerase II to produce pregenomic RNA which is translated allowing assembly of nucleocapsids from DHBcAg and packaging of pregenomic RNA and polymerase.

Pregenomic RNA is greater than genomic length due to a terminal redundancy (TR) of 243 nt (**Figs. 2 and 4**). Its packaging into nucleocapsids is facilitated by the presence of an encapsidation signal, epsilon (Σ), located near its 5' end (at nt 2566–2622) and again at the same position (2566–2622) within the 3' TR (**Fig. 4(A)**). Pregenomic RNA also contains DR1, a 12 nt sequence located 6 nt from the 5' end of the pregenome at nt 2541–2552 and at the same position (nt 2541–2552) in the 3' TR, where it is referred to as DR1*. The same 12 nt sequence is located upstream of DR1 at nt 2483–2494, where it is named DR2.

Fig. 4 DHBV DNA synthesis. Pregenomic RNA, which has a terminal redundancy (TR) of 243 nt plus a poly-A tail, has 2 potential encapsidation signals, epsilon (Σ), located at the 5' and 3' ends, but only the 5' copy is functional for pregenome encapsidation. Pregenomic RNA is packaged into nucleocapsids following binding of virus polymerase to the 5' Σ sequence. DNA synthesis then begins with reverse transcription of 4 nt of the bulge in the stem loop structure Σ , 5' UUAC 3' and leads to synthesis of the first 4 nt of negative strand DNA, 5' GTAA 3' as shown in B. Polymerase with the nascent transcript then translocates to the right hand copy of DR1, DR1*, and reverse transcription of the negative strand and degradation of the pregenomic RNA template by RNase H proceeds (C, D). Following completion of the negative strand, the 5' 18 nt of the pregenome, including the 5' cap and DR1, are typically translocated to DR2 and positive strand synthesis then initiates from this RNA primer. In this case, rcDNA formation is of necessity an early step in positive strand elongation (E, F). About 10% of the time, positive strand synthesis initiates without translocation of the primer (G), leading to the formation of dsIDNA (H).

Once the polymerase is translated, it may bind to its own message, pregenomic RNA, via the 5' Σ sequence, blocking its further translation, and facilitating packaging into nucleocapsids. DNA synthesis begins with reverse transcription of 4 nt (5' UUAC 3') in the bulge in the stem loop structure of Σ leading to synthesis of 4 nt of DNA (5' GTAA 3') (Fig. 4(B)). A tyrosine residue in the TP domain of polymerase serves as the primer of reverse transcription and the polymerase remains covalently attached to the 5' end of the newly formed 4 nt DNA sequence.

Following synthesis of the first 4 nt, the DNA-polymerase complex is translocated to DR1* (Fig. 4(C)), where the 4 nt can base pair due to sequence homology. Reverse transcription re-initiates and continues to the 5' end of the pregenome, to produce a full-length negative strand DNA with a 9 nt terminal redundancy. Most of the pregenomic RNA is degraded during negative strand elongation by the RNase H activity of polymerase (Fig. 4(D)). However, the 5' ~18 nt of the RNA pregenome, including the cap and all of the 5' copy of DR1, escapes RNase H degradation and serves as the primer for synthesis of the positive strand.

To facilitate positive strand synthesis, the ~18 nt RNA primer is first translocated to DR2, near the 5' end of the negative strand, where it hybridizes due to the sequence identity of DR1 and DR2 (Fig. 4(E)). Positive strand synthesis then occurs in a 5' to 3' direction to the 5' end of the negative strand template. Circularization then occurs to allow continuation of positive strand synthesis to produce mature rcDNA (Fig. 4(F)). This circularization is facilitated by the 9 nt TR on the negative strand template and the covalent attachment of the TP domain of the polymerase to the 5' end of the negative strand.

In ~10% of cases, translocation of the ~18 nt RNA primer from DR1 to DR2 does not occur and positive strand synthesis occurs by *in situ* priming, to produce dslDNA (Fig. 3, Fig. 4(G, H)). The dslDNA molecule has the 18 nt RNA primer at the 5' end of the positive strand and the polymerase covalently attached to the 5' end of the negative strand and is slightly longer than genome length.

Interestingly, the virus polymerase and the ~18 nt RNA primer remain associated with virus rcDNA and dslDNA genomes throughout virus assembly. Each nucleocapsid contains only a single copy of polymerase, supporting the model that a single protein molecule is simultaneously the TP primer of DNA synthesis and the polymerase for both RNA- and DNA-dependent DNA synthesis.

Nucleocapsids containing newly made rcDNA and dslDNA are enveloped by budding into the endoplasmic reticulum and exported as progeny virus via the Golgi, or are transported to the nucleus to make additional copies of cccDNA, typically found at 5–50 copies/hepatocyte (Fig. 3). DHBV cccDNA molecules exist within the hepatocyte nucleus as a population of virus minichromosomes that bind up to 20 nucleosomes. cccDNA does not undergo semi-conservative replication. New copies are therefore formed solely from rcDNA and dslDNA synthesized in the cytoplasm. However, formation of cccDNA from dslDNA involves illegitimate recombination and typically involves loss of sequences, so that the cccDNA formed from dslDNA is generally defective.

Nuclear transport of nucleocapsids containing rcDNA and dslDNA is negatively regulated by the virus envelope proteins, which direct nucleocapsids into the pathway of virus assembly. Negative regulation is essential because excessive accumulation of cccDNA will kill the host cell. Negative regulation may also be important because of the stability of cccDNA, and new synthesis of cccDNA may only be necessary to restore cccDNA levels in progeny cells following mitosis. Negative regulation of cccDNA synthesis also occurs during HBV infection, but it is not known if the HBV envelope proteins have an essential role in this process.

Nuclear transport of nucleocapsids containing dslDNA and, to a lesser extent, rcDNA, can also result in the integration of viral DNA at random sites in the cell chromosome via illegitimate recombination to create unique virus-cell DNA junctions (Fig. 3). Integrated forms of rcDNA and dslDNA are replication incompetent as they cannot be used to transcribe pregenomic RNA, which is greater than genomic length, and because virus sequences may be lost during the integration process, particularly from the ends of the dslDNA molecule. Integrated DNA has been detected in ~0.01%–0.1% of hepatocytes during transient HBV infections and higher levels accumulate during chronic HBV infections. Because integration occurs at random sites in host DNA, virus-cell DNA junctions can be used as molecular markers to identify and track the fate of individual hepatocyte lineages and possibly to gain insights into the development of primary hepatocellular carcinoma (HCC).

Epidemiology

DHBV is naturally transmitted *in ovo* from an infected female duck to the egg, with virus replication occurring in the yolk sac and liver of the developing embryo, leading to immune tolerance and congenital DHBV infection. Congenital infection is likely further facilitated because DHBV infection is not cytopathic. DHBV infections are therefore maintained within flocks and it is not unusual in some commercial flocks to find the presence of DHBV infection in 100% of birds.

DHBV infection can also be transmitted horizontally through parenteral exposure to infected blood and, since infection of adult ducks usually results in transient infection, duck flocks may contain a mixture of congenitally DHBV-infected and DHBV immune ducks. Female ducks that are immune to DHBV will have anti-DHBs and anti-DHBc antibodies circulating in their bloodstream as well as in the egg yolk which they can pass to their ducklings providing the newly hatched ducks with temporary resistance to DHBV infection.

Pathogenesis and Clinical Features

One major difference between DHBV and HBV are the clinical features of infection that result from differences in their mode of transmission and maintenance. DHBV is maintained primarily by *in ovo* transmission to the developing embryo, while HBV is maintained by horizontal transmission via infected body fluids from mother to child at birth or, during the first year of life, by transmission to the child from infected siblings or adults. Thus, both viruses cause persistent infection, but the degree of immune tolerance to DHBV is much greater following *in ovo* transmission than following horizontal transmission of HBV, which may be why immune responses to HBV-infected cells can lead to severe clinical outcomes of chronic HBV infection.

Humans with chronic HBV infection, if exposed to the virus at less than a year of age, often develop a “healthy carrier” state with high levels of virus replication and little liver disease. This healthy carrier state can last for 10–20 years but can progress to flares of immune-mediated liver disease with fluctuating levels of HBV DNA in the liver and bloodstream and chronic liver disease. If HBV infection is acquired in adulthood and chronic infection develops the accompanying immune-mediated liver disease is similar and can include inflammation, liver failure, fibrosis, cirrhosis, or HCC.

Following *in ovo* transmission congenitally DHBV infected ducks support virus replication in >95% of hepatocytes and have high levels of virus DNA and DHBsAg circulating in the bloodstream but this widespread infection generally results in an absence of clinical features and only mild, if any, hepatitis, similar to the “healthy carrier” state in humans. Interestingly, although >95% of hepatocytes remain infected, levels of DHBV DNA and DHBsAg in the bloodstream gradually decrease over 800 days. Whilst the cause of this gradual decline is unknown, anti-DHBc antibodies, which are usually detected within 7–14 days in experimentally infected adult ducks, are not detected until ~90 days post-hatch, consistent with a high degree of immune tolerance and the delayed activation of immune responses.

In summary, despite a high and persistent level of DHBV infection and replication, congenitally DHBV-infected ducks are immune tolerant to DHBV and progression to immune-mediated liver disease, cirrhosis and HCC have not been reported. Although HCC was detected in ducks in a Chinese province, aflatoxin exposure may have been common and the key contributory factor in the development of HCC. Amyloid disease of the liver is common in domestic ducks but does not appear to be linked to DHBV infection.

DHBV can also be transmitted experimentally to result in persistent or transient infection with clinical outcomes determined by the age of the ducks at the time of infection and the dose of virus inoculated. Experimental inoculation of newly-hatched ducks with DHBV invariably results in persistent infection with an absence of immune responses capable of clearing infection or producing chronic liver disease. In experiments where DHBV was titrated in newly-hatched (1-3-day-old) ducks, persistent infection was established by intravenous inoculation of pooled DHBV-positive serum containing the equivalent of ~ 1 virus genome. Virus spread throughout the liver to infect $>95\%$ hepatocytes within 28 days, showing not only that newly-hatched ducks are highly susceptible to DHBV infection but that the DHBV inoculum, which was derived from pooled sera from congenitally DHBV-infected ducks, had a high specific infectivity with a one-to-one ratio of infectious virus particles to DNA genomes. In related experiments in 3-day-old ducks inoculated with 1500 infectious doses of DHBV, infection was first detected in widely-scattered individual hepatocytes, then in pairs and small groups of cells and resulted in infection of $>95\%$ hepatocytes within 13–15 days. Spread of virus occurred both to adjacent hepatocytes presumably by spread within the space of Disse (cell-to-cell spread) and via the blood by release of virus into the liver sinusoids.

Susceptibility to persistent DHBV infection declines with age. As ducks increase in age, larger doses are required to establish persistent infection, consistent with the idea that larger doses of virus are required to overwhelm the developing immune system: inoculation of 2-week-old ducks with 4×10^4 infectious doses of DHBV resulted in infection of randomly-scattered hepatocytes with subsequent virus clearance. Increasing the dose to 1×10^6 resulted in virus spread to $>95\%$ of hepatocytes and persistent infection. As the age of the duck further increases, larger doses are required to establish persistent infection: inoculation of 6-week-old ducks with $1.5\text{--}4.5 \times 10^{10}$ infectious doses of DHBV resulted in transient infection with successful clearance of infected hepatocytes and accompanying increases in activated Kupffer cells and apoptotic hepatocytes in 11 out of 16 ducks, while the remaining 5 ducks developed persistent infection. Persistent infection was accompanied by mild mononuclear cell infiltration of portal tracts, but no evidence of lobular hepatitis or extensive liver damage was seen within a 1-month timeframe.

While showing that susceptibility to persistent infection decreases with age, these studies also raised the question of how the immune system can clear an infection in which virtually all hepatocytes are infected. This is a problem because under most circumstances, including DHBV clearance, the hepatocyte population is mostly self-renewing. This has been partially resolved by subsequent experiments in DHBV-infected ducks, woodchuck hepatitis virus-infected woodchucks and HBV-infected chimpanzees.

Current understanding is that the “clearance phase” of transient hepadnavirus infection involves 3 steps: (1). A strong CD8-positive CTL response that kills a large fraction of infected hepatocytes, with direct loss of replicative intermediates and cccDNA; (2). A concurrent CTL-induced interferon-gamma response that eliminates nucleocapsids containing replicating DNA from surviving hepatocytes; and (3). Since hepatocytes are a largely self-renewing population, proliferation of surviving hepatocytes to restore liver cell mass. In this way hepatocytes that survive give rise to the uninfected hepatocytes that populate the liver at recovery. What has remained unclear is the fate during this “clearance phase” of the 5–50 copies of cccDNA present in the nucleus of infected hepatocytes; in particular, those hepatocytes not killed by anti-viral CTL. On one hand there is evidence to suggest that cccDNA elimination requires the turnover of the infected hepatocytes (modeling studies have shown that if cytokines eliminate nucleocapsids containing replicative DNA, and cccDNA survives mitosis, cccDNA-free hepatocytes will be generated by dilution of cccDNA through 2–3 turnovers of the entire hepatocyte population, while if cccDNA does not survive mitosis, generation of cccDNA-free hepatocytes would require <1 turnover). On the other hand, published evidence also suggests that cytokine-mediated effects might lead to loss of cccDNA; whether this is a significant effect *in vivo* and sufficient to explain cccDNA loss during virus clearance remains unclear.

Although hepatocytes are the main cell type infected by DHBV, infection also occurs in extrahepatic tissues. In ducks infected *in ovo*, with transmission of DHBV from the bloodstream of the female duck to the egg, virus replication first occurs in the endodermal yolk sac, then in the developing liver and pancreas of the embryo (Fig. 5(A–C)). In the liver, hepatocytes and bile duct cells are infected with DHBV and express high levels of DHBcAg and DHBsAg. Virus replication also occurs in scattered acinar cells and in alpha and beta endocrine islet cells in the pancreas, and in glomeruli and tubular epithelial cells in the kidney of developing embryos. Similar patterns of extrahepatic DHBV infection also occur following experimental transmission in ducklings (Fig. 5(C–E)). Viral antigen accumulation in kidney glomeruli many represent bound immune complexes. Cells located in the red pulp and germinal centers of the spleen have been shown to contain DHBV DNA. Mononuclear cells in the red pulp support DHBV replication early after infection while germinal centers contain non-replicating DHBV DNA associated with follicular dendritic cells. Overall, the significance of viral replication in extrahepatic tissues to the pathogenesis of DHBV infection remains unclear.

Diagnosis

In ducks with congenital and persistent DHBV infection, where $>95\%$ of hepatocytes are infected, DHBV virions are released into the bloodstream resulting in titers of up to 1×10^{10} virions/ml. 35–60 nm DHBsAg particles that lack a virus nucleocapsid are also released from infected hepatocytes, in 500–1000-fold excess over virions, resulting in $\sim 5\text{--}50$ ug/ml of DHBsAg. Serum samples can be tested for DHBV DNA by PCR and for DHBsAg using enzyme-linked immunosorbent assay (ELISA). DHBV

Fig. 5 Hepatic and extrahepatic DHBV infection. Immunoperoxidase staining of DHBcAg in yolk sac (A), liver (B, E), pancreas (C, F) and kidney (D). DHBV is transmitted *in ovo* from the bloodstream of a DHBV-infected female duck to the egg resulting in DHBV infection in (A) yolk sac cells, (B) liver hepatocytes and bile duct cells (arrow) and (C) pancreatic acinar cells in a 14-day fertilized duck embryo. DHBV infection was also detected in (D) kidney glomerular cells (arrow), (E) liver hepatocytes and bile duct cells (arrow) and (F) pancreatic acinar and islets cells (arrow) in a 2-week-old congenitally DHBV-infected duck. Ethanol:acetic acid-fixed tissues were immunostained with polyclonal anti-DHBc antibodies and counterstained with haematoxylin. Magnification $\times 226$. Bar = 50 μ m.

infection can also be detected by immunoperoxidase or immunofluorescence staining of ethanol:acetic acid-fixed and frozen liver tissue using monoclonal or polyclonal anti-DHBs or anti-DHBc antibodies or by using PCR techniques to detect DHBV DNA in extracts from liver and extrahepatic tissues. Detection of cccDNA is performed by selective extraction of protein-free DNA followed by detection by Southern blot hybridization or by a specific PCR assay for cccDNA with primers spanning the incomplete region of the rcDNA genome to reduce detection of rcDNA and replicative intermediates.

DHBsAg and DHBcAg proteins are highly immunogenic. Anti-DHBc antibodies can be detected by ELISA in the serum of ducks during transient and persistent DHBV infections. Anti-DHBs antibodies are produced during the resolution phase of transient infection and are generally not detected in ducks with persistent infection except in complexes with circulating DHBsAg. Anti-DHBs antibodies bind virus particles and are able to block DHBV infection of cells. For this reason, ducks that have recovered from transient infection are immune to challenge with DHBV.

Cellular immune responses that occur during DHBV infections are more difficult to study due to a lack of reagents for studying the immune system in the duck; however, *in vitro* stimulation assays for detection of viral antigen specific T-cell responses have been developed and anti-duck CD4 and CD8 monoclonal antibodies are available for further studies. The recent cloning of cDNA for the duck interferon- α and γ , duck T-cell markers including CD3, CD4, CD8, MHC I and II and duck TLRs now increase the feasibility of studies of the immune response during DHBV infection.

Treatment

Because of its reproducible kinetics and predictable outcomes of infection, the DHBV model has been widely used for the evaluation of anti-viral therapies. Similarities in the replication strategy and structure and activity of the HBV and DHBV polymerase enzymes have allowed anti-viral drugs designed for chronic HBV to be evaluated, either as monotherapy or in combination, in DHBV-infected ducks. A range of nucleoside and nucleotide analogs (NA), that inhibit replication by acting as chain terminators, have been tested including ganciclovir, penciclovir, adefovir, entecavir (ETV), tenofovir disoproxil fumarate (TDF), emtricitabine and clevudine. Treatment of DHBV-infected ducks with NA blocks reverse transcription and inhibits the synthesis of rcDNA and dsDNA in the cytoplasm of infected cells. However, cccDNA, which is present at 5–50 copies in the nucleus of each infected cell at the outset of treatment, is often reduced (presumably by hepatocyte turnover) but not eliminated, and since cccDNA is the template for transcription of viral RNA, viral antigen expression also persists, and virus replication can rebound if treatment is discontinued. A further issue is the high error rate of the viral polymerase, which can introduce mutations into the polymerase RT domain, allowing the emergence of drug-resistant DHBV strains. Some NA (*e.g.*, ETV and TDF) can be used in monotherapy in treatment naïve patients, but long-term anti-viral therapy for chronic HBV infection more commonly uses combinations of different NA to lower the risk of emergence of multidrug-resistant HBV strains. Newer direct-acting anti-viral agents as well as immunomodulators are also in development for chronic HBV infection.

Studies of anti-viral therapy in the DHBV model have demonstrated the stability and long *in vivo* half-life of cccDNA. It is not surprising therefore that cccDNA persists in trace amounts following the resolution of transient HBV infection and that infection

can rebound in situations of immune depletion; for example, during immune suppression following transplantation with donor liver containing residual HBV cccDNA. Studies in the DHBV model have shown that levels of cccDNA present in the liver following the resolution of transient infection are unaffected by treatment with ETV, indicating that residual cccDNA is highly stable and is present in a cell population with a low rate of turnover as compared to typical hepatocytes. The stability and persistence of cccDNA has also been studied in the liver of newly-hatched ducks in which high levels of hepatocyte mitosis occur due to liver growth. Although these results suggested that cccDNA could survive hepatocyte mitosis, there was large duck-to-duck variation in cccDNA levels suggesting that despite therapy with ETV, cccDNA may be maintained to some extent by low levels of viral DNA replication in the growing liver.

DHBV-infected ducks have also provided a model system for anti-viral drug therapy in combination with DNA vaccines and have been used to assess nucleic acid polymers developed by REPLICor Inc (which function as broad spectrum anti-viral agents by inhibiting the release of HBsAg from hepatocytes) to protect against and as therapy for persistent DHBV infection.

The identification and cloning of the cellular receptor used by HBV, hNTCP, and the ability to express the hNTCP in mammalian cells, has conferred susceptibility to HBV infection on a whole range of transformed cell lines and will enable studies of anti-viral drugs, virus replication and cccDNA to be performed *in vitro* in cell lines infected with HBV. These systems are likely to decrease reliance on the DHBV model, but are unlikely to replace the model, which allows studies of the complex interplay between host and virus factors during *in vivo* infection.

Endogenous Avian Hepadnavirus Elements

Recent advances in computational genomics have led to the discovery of endogenous avian hepadnavirus elements in the germline of many bird species, representing most of the major bird orders. Endogenous avian hepadnavirus elements were first identified in the zebra finch (*Taeniopygia guttata*, family Estrildidae) and designated as endogenous zebra finch HBV (eZHBV). eZHBVs have been detected on 10 different chromosomes as site-specific integrated viral fragments that cover ~70% of the avian hepadnavirus genome. eZHBVs have also been found in three other estrildid finches: the black throated finch (*Poephila cincta*), the scaly breasted munia (*Lonchura punctulata*) and the Gouldian finch (*Erythrura Gouldiae*) and in the rough-legged hawk (*Buteo lagopus*) and the black-headed gull (*Chroicocephalus ridibundus*). Endogenous avian hepadnavirus elements have also been found in the dark-eyed junco (*Junco hyemalis*, family Emberizidae) and designated as endogenous Junco HBV (eJHBV). The first full-length endogenous avian hepadnavirus elements were found in the genome of the budgerigar (*Melopsittacus undulatus*, family Psittaculidae) and, along with additional partial genome fragments, were named endogenous budgerigar HBV (eBHBV) (Table 1B). Partial and full-length eBHBVs do not share site-specific orthologous integration points with the identified eZHBVs and, like the individual eZHBVs, represent separate integration events.

All of the eZHBV, eJHBV and eBHBV sequences described to date have lost their AUG start codons or contain stop codons or missense mutations that would prevent them from encoding functional proteins. However, analysis of the putative polymerase AA sequences of eZHBV, eJHBV and eBHBV shows that they are related to, but distinct from the exogenous avian hepadnaviruses, AusDHBV, SGHBV1-7, CCHBV1, RGHV, ETHBV, PHBV-A, STHBV-1 and HHBV-4 (Fig. 1(B)).

Phylogenetic analysis suggests that endogenous avian hepadnavirus elements were created through multiple integrations of rcDNA or dsDNA into germline DNA earlier in evolutionary history when the species, or an ancestor, supported exogenous avian hepadnavirus infection. Integration of hepadnavirus DNA into the host genome occurs at a random site and, once fixed in the host germline, the site-specific integration is passed on to progeny by long-term vertical inheritance and can be used as a genetic marker of ancestry. For example, eZHBVs, which were the first endogenous viral elements to be described from a reverse transcribing DNA virus, revealed a deep timescale of the association between hepadnaviruses and birds. The detection of eZHBV sequences in

Fig. 6 Evolution of endogenous avian hepadnavirus elements. (A). Endogenous avian hepadnavirus elements reveal a long association between hepadnaviruses and birds. Presence/absence analyses of eZHBV insertion loci revealed eZHBV endogenization events in the ancestor of Neoaves, during early passeroid evolution and during recent ploceid evolution. The youngest eZHBV (eZHBV_M) was found in the zebra finch but not in the Gouldian finch, weaver, pipit, rosefinch, dunnock, leafbird or sunbird, placing its endogenization after the speciation of the zebra finch in the Miocene, 12.1 million years ago (MYA). Five distinct site-specific orthologous eZHBVs integrants (eZHBV_O1-eZHBV_O5) have been identified during the Oligocene (26.6–34.2 MYA) based on their presence in the finch, but not in the leafbird or sunbird, and one (eZHBV_E) during the Eocene (34.2–35 MYA) which was found in finches and the leafbird but not in the sunbird. The oldest eZHBV integrant (eZHBV_C) is believed to have integrated into a zebra finch ancestor between 82 and 94 MYA, during the Cretaceous Period. The avian tree of life is shown as a simplified chronogram based on molecular dates of interordinal avian relationships, as well as relationships within Passeriformes and Ploceidae. Nucleotide substitution rates (substitutions/site/year) based on HAS (hypothetical ancestral sequences) were calculated for the respective parts of eZHBV evolution and denoted above the tree. Endogenization events are depicted as icosahedrons and temporal ranges of insertion events are shown as colored rectangles. Colored scale at the bottom bar represents millions of years. Reproduced from Suh, A., Brosius, J., Schmitz, J., Kriegs, J.O., 2013. The genome of a mesozoic paleovirus reveals the evolution of hepatitis B viruses. *Nature Communications* 4, 1791, Fig. 1, with permission. (B). Distribution of endogenous avian hepadnavirus elements across the avian phylogeny. Chromosome and whole DNA genome shotgun assemblies of 48 avian species were screened in silico using tBLASTn with a library of hepadnavirus protein sequences. 46 out of 48 host species generated high-identity matches to hepadnavirus proteins and are marked in red on the species tree, while 2 DNA samples were negative and are marked in white. The phylogeny is based on the results of a phylogenomics consortium whole DNA genome analyses across all the species shown. Reproduced with modifications from Cui, J., Zhao, W., Huang, Z., et al., 2014. Low frequency of paleoviral infiltration across the avian phylogeny. *Genome Biology* 15 (12), 539, Fig. 1, with permission.

different avian species is illustrated in Fig. 6(A) (reproduced with permission Suh et al., 2013). The youngest eZHBV integrant to be described (eZHBV_M; corresponding to 15% of the avian hepadnavirus genome) is thought to have integrated into the germline genome of a zebra finch ancestor in the Miocene, 12.1 MYA. Five additional integration events have been identified for eZHBVs (eZHBV_O1-eZHBV_O5; 3.3%–9.0% of the avian hepadnavirus genome) during the Oligocene (26.6–34.2 MYA), and one (eZHBV_E; 14.8% of the avian hepadnavirus genome) during the Eocene (34.2–35 MYA). The oldest eZHBV integrant to be dated so far (eZHBV_C; 99% of the avian hepadnavirus genome) is believed to have integrated between 82 and 94 MYA, during the Cretaceous Period. The detection of eZHBV_C in all major taxa of Neoaves (which includes most modern birds) and its absence in non-Neoaves (e.g., the chicken and the ostrich) places the time of integration after the separation of Neoaves and non-Neoaves but before the diversification of Neoaves.

Mining of whole genome sequence data recently made available for 48 bird species (representing thirty-two of thirty-five proposed bird orders and including all Neoavian orders) has revealed the widespread presence of endogenous avian hepadnavirus

elements. As can be seen in **Fig. 6(B)** (adapted and reproduced from Cui *et al.*, 2014), endogenous avian hepadnavirus elements were detected in 46 out of 48 species including the zebra finch and budgerigar as previously discussed, but also detected in species that support exogenous avian hepadnavirus infection including the Grey crowned crane and the mallard, the species from which most domesticated ducks are derived. The diversity of avian species containing endogenous avian hepadnavirus elements suggests that multiple integrations have occurred over the evolutionary history of birds.

Acknowledgments

The authors wish to acknowledge Dr William Mason for critical reading of the manuscript and helpful discussions, and Ms Tahlia Perry and Prof Frank Grutzner for assistance with the phylogenetic analysis.

Avian Herpesviruses (*Herpesviridae*)

Vishwanatha RAP Reddy and Venugopal Nair, The Pirbright Institute, Pirbright, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Classification

Avian herpesviruses (AHV) are widespread among most variety of domestic, wild and captive bird species. Similar to mammalian herpesviruses, most AHV have narrow host range in their natural hosts, although some of these viruses infect different bird species belonging to the same or to unrelated families or even orders. Based on the International Committee on Taxonomy of Viruses (ICTV), AHV are classified as alphaherpesviruses, under subfamily *Alphaherpesvirinae*, family *Herpesviridae* and order *Herpesvirales*. These viruses include Gallid herpesvirus type 1 (GaHV1) and Psittacid herpesvirus type 1 (PsHV1) that belong to the genus *Iltovirus*, and Gallid herpesvirus type 2 and 3 (GaHV2 and 3), Meleagrid herpesvirus 1 (MeHV1), Anatid herpesvirus 1 (AnHV1) and Columbidae herpesvirus 1 (CoHV1) that belong to the genus *Mardivirus*.

Several taxonomically unassigned AHV were also identified in a wide variety of birds, such as falcons (Falconid herpesvirus 1, FaHV1), cranes (Gruid herpesvirus 1, GrHV1), cormorant (Phalacrocoracid herpesvirus 1, PhHV1), eagles (Accipitrid herpesvirus 1, AchHV1), storks (Ciconiidae herpesvirus 1, CiHV1), owls (Strigid herpesvirus 1, StHV1), quails (Perdidae herpesvirus 1, PdHV1), penguins (Spheniscidae herpesvirus 1, SpHV1) and loons (Gaviidae herpesvirus 1, GavHV1) (Fig. 1). Additional AHV infections have also been reported in several wild- and free-range bird species such as the prairie falcon, red-headed falcon, little pied cormorant, demoiselle cranes, Sudan crowned cranes, paradise cranes, Japanese cranes, hooded cranes, black storks, American white storks, black-footed penguin, satyr tragopan, toucans, and many passerine birds.

Fig. 1. Genetic relationship of avian herpesviruses with other alphaherpesviruses based on 44 592 amino acid sequences of 52 core genes of the viruses is shown. Gallid herpesvirus 1 (GaHV1) and Psittacid herpesvirus 1 (PsHV1) are closely clustered under *Iltovirus* genus. Gallid herpesvirus 2 and 3 (GaHV2 and 3), Meleagrid herpesvirus 1 (MeHV1), Anatid herpesvirus 1 (AnHV1) and (Falconid herpesvirus 1, FaHV1) are closely grouped under *Mardivirus* genus. Above figure adapted from Pfaff, F., Schulze, C., König, P., et al., 2017. A novel alphaherpesvirus associated with fatal diseases in banded Penguins. *Journal of General Virology* 98, 89–95. doi:10.1099/jgv.0.000698.

Most AHV of wild or free-range birds have been named according to the species of the avian hosts. However, a number of others in wild- and free-range birds still remain as nameless orphan AHV. In some cases, AHV are named after the pathological characteristics associated with the diseases or in honor of scientists who first reported it. Examples include infectious laryngotracheitis virus (ILTV or GaHV1), duck enteritis virus (DEV or AnHV1), hepatosplenitis infectiosa strigum virus (HSIS or StHV1), inclusion body disease virus (FaHV1, GrHV1 and AchV1), herpesvirus of turkeys (HVT or MeHV1), Pacheco's parrot disease virus (PPDV or PsHV1), Marek's disease virus (MDV or GaHV2), and Smadel's disease virus (CoHV1). This article mainly will focus on ILTV, PPDV, MDV and DEV. For information on other AHV, please refer to further reading details.

ILTV is a highly contagious respiratory virus of chickens that is transmitted by inhalation, direct bird-to-bird contact and indirectly through fomites and people. ILTV actively replicates in the epithelium of larynx, trachea and conjunctiva, leading to severe epithelial damage, hemorrhages and laryngotracheitis (hence the term 'infectious laryngotracheitis'). After an acute phase of infection, characterized by clinical signs such as nasal discharge, conjunctivitis and drop in egg production, ILTV establishes a lifelong latency in the trigeminal ganglion. During severe forms of the disease, additional signs such as gasping, expectoration of bloody mucus, dyspnea and death due to asphyxia are also observed. Major economic impact of ILT comes from production losses, high morbidity and mortality and from the costs of vaccination. Live attenuated and recombinant viral vectored vaccines are available to protect against ILT. Most outbreaks are associated with reversions of the live vaccines strains to a virulent strains.

Pacheco's parrot disease virus (PPDV) or Psittacine herpesvirus 1 (PsHV1) is a highly contagious, and potentially fatal respiratory virus of psittacine birds, characterized by acute necrotizing lesions of the crop, intestines, liver and pancreas. Pacheco's parrot disease (PPD) has been reported in psittacine birds in most geographical locations of the world, and is a major concern in the captive parrots of exotic collections. Amazon parrots, cockatiels, Roselle, Galah and macaws are some of the worldwide affected bird species of the PPDV. PPDV outbreaks commonly occur in the quarantine stations and markets, where parrots are held in close proximity. Thus, worldwide exotic pet breeders and companion bird markets are of great concern about the PPD. Other types of psittacine herpesviruses distinct from PsHV1 such as psittacid herpesvirus 2 and 3 have been identified, serotyped and phylogenetically characterized.

Marek's disease virus (MDV-1) or Gallid herpesvirus 2 (GaHV2) is a contagious oncogenic virus, causes neoplastic and neuropathic disease in chickens, commonly known as Marek's disease (MD). Only, MDV-1 causes clinical oncogenic disease in chickens. Gallid herpesvirus 3 (GaHV3) and herpesvirus of turkeys [HVT or Meleagrid herpesvirus 1 (MeHV1)] are non-oncogenic apathogenic herpesviruses of chickens and turkeys, respectively. GaHV3 and HVT are usually used as the live vaccines against pathogenic MD.

Duck enteritis virus (DEV) or Anatid herpesvirus 1 (AnHV1) is a highly contagious virus of waterfowl species such as ducks, geese and swans, which causes acute disease called duck viral enteritis (DVE), sometimes also referred to as duck plague. Waterfowls of all ages are susceptible to DEV and the disease is characterized by vascular damage, tissue hemorrhages, lymphoid organ lesions, digestive mucosal eruptions, degenerative changes in parenchymatous organs and death. DVE causes significant economic losses in domestic and wild water fowls due to mortality, reduced egg production and meat condemnations. Total morbidity and mortality may range from 5% to 100%.

Host Range

Many AHV appear to be group-specific in a given bird species and exhibit a very narrow host range. Chickens are the primary natural hosts of ILTV, although pheasants, pheasant-chicken crosses and peafowls are also infected with this virus. ILTV is commonly isolated and propagated in the embryonated chicken eggs, where it induces opaque plaques on the chorioallantoic membrane (CAM) resulting from necrosis and proliferation of the infected cells. Plaques on CAM can appear as early as two days post-inoculation (PI) and embryo deaths occur between 2 and 8 days PI. ILTV can also be propagated in a variety of primary avian cell cultures such as chicken embryo kidney (CEK), chicken embryo liver (CEL), chicken embryo lung and chicken kidney cells (CKC), as well as in the LMH (leghorn male hepatoma) cell line. PsHV1 grows in primary chicken embryo fibroblasts (CEF) cultures where it readily shows syncytial plaques. MDV-1 is routinely propagated in CEF, embryonic CKC, and/or duck embryo fibroblasts (DEF). Several lymphoblastoid cell lines that grow continuously as suspension cultures have been developed from MD lymphomas. These cell lines are routinely used to understand the pathobiology of MD lymphomas.

Virion Structure

Broadly AHV have hexagonal nucleocapsids with icosahedral symmetry, with typical morphological features of herpesvirus particles. The 80–125 nm in diameter icosahedral nucleocapsids is made of elongated hollow 162 capsomers-150 hexamers and 12 pentamers. Overall diameter of the enveloped virus can vary. ILTV with irregular envelope has a diameter of 195–250 nm, while the enveloped MDV particles are around 150–160 nm. In general, the morphologies of members of the *Mardivirus* are similar, although HVT capsids appear to show a unique crossed appearance.

Genome

AHV isolates have linear double stranded DNA genomes of approximately 150–200 kilobase pairs (kbp). Based on the genome organization, herpesviruses are classified in to six different groups A to F including class D (ILTV and PsHV1) or E (MDV-1, GaHV3

and HVT) genomes. Class D herpesvirus genomes consist of long and short unique regions (U_L and U_S) interspersed with inverted repeat sequences, such as internal repeat (IR) and terminal repeat (TR) sequences. Class E herpesvirus genomes, consist of unique long (U_L) and unique short sequence (U_S), flanked by a sets of inverted repeat sequences: the terminal repeat long (TR_L), internal repeat long (IR_L), internal repeat short (IR_S), and terminal repeat short (TR_S), respectively.

The 153-kbp ILTV genome, predicted to have 79 open reading frames (ORFs), has a 47.9% G+C content, while the 163-kbp PPDV genome, with 73 predicted ORFs, has a 60.9% G+C content. The majority of ILTV and PPDV ORFs have homologous ORFs in other alphaherpesviruses, such as HSV1. However, many unique ORFs also do exist in the ILTV and PPDV genomes. For example, ORFs A, B, C, D, E, F, U_L0 and U_L1 are largely specific of ILTV and PPDV. A large internal inversion of U_L22 to U_L44 genes within the U_L segment has been also reported to be specific to ILTV and PPDV genomes. U_L47 , a conserved homolog among alphaherpesviruses, is absent at the corresponding positions of ILTV and PPDV genomes, but a homolog with weak identity (18%) is found to be inserted between the U_S3 and U_S4 genes of U_S region. ILTV and PPDV genomes also have differences in gene organization, for example, a U_L16 homolog that is conserved throughout all herpesviruses, is absent in ILTV but present in PPDV. In contrast, ILTV contains U_L48 , U_L0 ORFs and U_S9 , neither of which are present in PPDV. Further, the ILTV inverted and terminal repeats are 2535 bp (18.5%) shorter than the PPDV, and each repeat consists of three genes: ICP4, U_S10 and a homolog of the MDV sORF4/3. Conversely, only ICP4 is present in inverted and terminal repeats of PPDV, U_S10 and sORF4/3 are present in U_S region.

The full genome sequences of MDV, GaHV3 and HVT are very similar of approximately 160–180 kb with a varying G+C content of ~43.9%, ~53.6% and ~47.6%, respectively. A total of 103 ORFs in MDV genome, 102 in GaHV3 and 99 in HVT were clearly identified, in addition to a number of microRNAs. The majority of U_L and U_S genes of *Maridiviruses* are homologous to the genes encoded by the alphaherpesviruses. Many virus-specific genes have been identified, and are located predominantly in the IR_L and TR_L regions. Meq (MDV EcoRI Q), vIL8 (viral interleukin 8), vLIP (viral lipase), pp38/pp24 and vTR (RNA telomerase subunit) genes have been identified that are unique for MDV. The Meq gene encodes a 339-amino acid oncoprotein, which contains a basic leucine zipper (bZIP) transcriptional regulator domain at the N terminal and the proline rich repeat transactivator domain at the C terminal. The Meq protein is expressed consistently in the nucleus of lymphoma cells and tumor cell lines. The vIL8 gene is located in the long repeat region, and originally was identified as a spliced Meq variant. The vIL8 functions as a chemoattractant for chicken mononuclear cells, and may be important for the switch of infection from B to T lymphocytes. The vLIP gene, required for efficient lytic replication, encodes a soluble N glycosylated protein similar to α/β beta fold of pancreatic lipases. MDV-1 genome encodes the pp38/pp24 complex within the TR_L/IR_L and the U_L region. MDV-encoded vTR gene, with nearly 88% sequence identity to the chicken telomerase RNA (cTR) indicating its transduction from the host genome, is present in the IR_L/TR_L region of the MDV genome. HVT encodes a two copies of vNr13 protein, a Bcl2 homolog, not seen in the other alphaherpesviruses. The vNr13 is strikingly similar to chicken Nr13 protein (63.7% amino acid identity), an anti-apoptotic member of the Bcl2 like proteins. Most DEV strains have approximately of 160-kbp long genome with a G+C content of 44.89%. With around 78 ORFs, many are homologs seen in other alphaherpesviruses. Five DEV genes were unique among the AHV, while three appear to be specific to DEV.

Replication Cycle

The replication cycle of ILTV is similar to other alphaherpesviruses, which usually starts with the initial attachment to cell surface, which is enhanced by viral glycoproteins gB, gD and gH-L complex. After initial attachment, the nucleocapsid is released into the cytoplasm and transported to the nucleus. Upon injection of the viral genome in the nucleus via the nucleopore, viral DNA replication and transcription occur. In general, the alphaherpesvirus genome transcription strictly follows a regulated cascade at different time points grouped into immediate early (IE), early (E) and late (L) genes. Commonly, IE and E genes, and their products regulate transcription of L genes. First several enzymes and DNA binding proteins are expressed, which are required for DNA replication, e.g., DNA polymerase and thymidine kinase. This is followed by the expression of viral structural proteins such as the capsid, tegument and envelope glycoproteins. The newly synthesized DNA concatemers cleaves into monomeric units and assemble with capsids to form nucleocapsids in the nucleus. The assembled nucleocapsids exploit an envelopment/de-envelopment pathway for transport to the cytosol. The nucleocapsids acquire an envelope by budding through the inner leaflet of the nuclear membrane. The primary enveloped nucleocapsids, undergo a fusion with the outer nuclear membrane, leading to the release of de-enveloped/naked nucleocapsids into the cytoplasm. In the cytoplasm, main tegument proteins are added to the nucleocapsids, before obtaining their final envelope by budding into the Golgi-derived vesicles. Enveloped mature virions released into the extracellular space by exocytosis/cell lysis and membrane vacuolar fusion.

The replication cycle of *Maridiviruses* are similar to other cell-associated herpesviruses such as varicella zoster virus (VZV). The precise virus entry, attachment and replication pathways of MDV remains still unsolved because of strict cell-associated nature of the virus, and only few steps of the replication cycle are available. US3-kinase has been reported to be involved in the morphogenesis as well as cell-to-cell spread of virus through the effect on stress fiber breakdown and polymerization of actin. The glycoproteins gE, gI and gM play a role in the transfer of virus from infected to uninfected cells.

Epidemiology

Majority of AHV are highly contagious especially in intensive production system where the viruses are transmitted very efficiently between birds. Many AHV appear to be group-specific in a given bird species and exhibit a very narrow host range, suggesting their co-

evolution over millions of years. Chickens are the primary natural hosts of ILTV, although pheasants, pheasant-chicken crosses and peafowls are also infected with this virus. Phylogenetic analysis have suggested that AHV species such as ILTV and PsHV-1 have separated from mammalian alphaherpesviruses around 200 million years ago, and have been co-evolving since then with their specific hosts. PsHV1-infected birds shed the virus from the oral or respiratory secretions and droppings. As in the case of ILTV infection, PsHV1 is transmitted by direct bird to bird contact or indirectly by contact with contaminated fomites or environment. Latent virus persists in the flock over generations, and act as source of new infection following reactivation during stress with factors such as the onset of egg laying and mixing of chickens. ILTV has been also reported in extra respiratory tissues like liver, spleen, kidneys, heart, intestines, bursa Fabricius and Harderian glands. Epidemiology of ILTV is also affected by their ability for potential recombination. Water appears to be the natural means of DEV transmission among infected water fowls. DEV establishes latency in the TG and lymphoid tissues including peripheral blood lymphocytes, and recovered waterfowls become carriers and shed the virus intermittently.

Viruses such as MDV mainly infects chickens, although quails, turkeys and pheasants are also susceptible to the disease. Because of their long-term survival in the infected environment in the poultry house dust, coupled with continuous shedding from dander and dust in the latently-infected hosts, diseases such as MD are difficult to be eradicated from the infected flocks. While vaccination still continues to be the most effective approach for control of MD, the leakiness of the current vaccines due to their inability to prevent virus shedding has been thought to be one factor driving virulence of the MDV strains.

Clinical Features

Clinical features of AHV infections vary between viruses and tissues targeted by different viruses. ILTV-associated diseases range from mild to severe forms. The mild form of the disease is characterized by nasal discharge, mild conjunctivitis, mild respiratory rales, reduced egg production and no mortality, while the severe form is characterized by open mouth breathing with expectoration of bloody mucoid material, severe conjunctivitis, high morbidity, and moderate to severe mortality. The clinical signs are reported in chickens of all ages but the most characteristic are observed in adult birds. The important gross pathological changes of ILT include hemorrhages and diphtheritic changes in larynx and trachea, with mucoid plugs/casts in the trachea and presence of eosinophilic inclusion bodies in mucosal cells.

Clinical signs of PPD include anorexia, depression, nasal discharge, diarrhea, tremors and instability. The majority of infected birds die very rapidly before the onset of clinical signs. Gross pathological lesions include abnormal changes in the respiratory, muscular and circulatory system, bone marrow, thyroid and adrenal glands, liver, spleen, kidneys, the urogenital and gastrointestinal tract, and the nervous system. Histopathological changes include necrotizing lesions in many organs, hemorrhages and congestion of the liver, spleen and kidneys, and the presence of intranuclear inclusion bodies.

Clinical manifestations of MD vary according to the specific syndromes. In general, the classical form of the disease is characterized by unilateral paralysis of the legs and/or wings. In acute forms of disease with visceral lymphomas, affected birds may appear clinically normal but have extensive neoplastic involvement visible on post-mortem examination. Non-specific signs such as weight loss, paleness, anorexia, and diarrhea may also be seen in the chickens affected with lymphomas. The incidence of MD is quite variable in commercial flocks and in general are low since the introduction of vaccination. Severely affected peripheral nerves may show loss of cross-striations, yellow discoloration and edematous appearance. Lymphomas may occur in a variety of visceral organs. Lymphomas can be found in the lung, spleen, bursa, thymus, heart, adrenal gland, kidney, liver, mesentery, proventriculus, intestine, iris, skeletal muscle, skin and gonads. Microscopically two main types of lymphoproliferative lesions are recognized in peripheral nerves. Type A lesions are considered as neoplastic mainly consisting of CD30⁺ CD4⁺ T cells. Demyelination and Schwann cell proliferation of peripheral nerves are also observed in type A lesions. Type B lesions are mostly inflammatory, characterized by diffuse, light to moderate infiltration of lymphocytes and plasma cells. MD lymphomatous lesions in MD are more proliferative than those in nerves. Appearance is similar to type A lesions, mainly consist of T lymphocytes and lymphoblasts, B cells, macrophages and natural killer cells (NK cells). Majority of transformed T cells express CD4 and MHC II.

In mature breeder duck flocks acutely infected with DEV, sudden, high and persistent mortality with drop in egg production have been reported. As infection progresses, other signs such as loss of appetite, ataxia, photophobia, associated pasted eye-lids, droopiness, ruffled feathers, nasal discharge and watery diarrhea are observed. Characteristic lesions of DVE are intravascular coagulopathy and necrotic degenerative changes in mucosa and submucosa of gastrointestinal tract in lymphoid and parenchymatous organs. Petechial or larger extravasations of blood may be found or in the myocardium and other visceral organs. Liver, pancreas, intestine, lungs, and kidney surfaces may be covered with petechial hemorrhages. Mucosal lesions are observed in the oral cavity, esophagus, ceca and cloaca. Microscopically, initial lesions occur in the walls of blood vessels. The endothelial lining is disrupted and connective tissue of the wall becomes less compact. Eosinophilic intranuclear and cytoplasmic inclusions are observed in epithelial cells of digestive tract.

Pathogenesis

Pathogenesis of AHV can differ based on their tissue tropism and diseases. ILTV enters its host through upper respiratory and ocular routes, and then primarily replicates in the epithelium of larynx, tracheal and conjunctival mucosae, respiratory sinuses, air sacs and lungs. During the first 7 days of infection, ILTV replication in the larynx and trachea, leads to epithelial damage and hemorrhages. Several authors have reported that active replication of ILTV slows down after 6 days post inoculation (dpi), and virus may remain at very low levels up to 10 dpi. ILTV infection spreads to trigeminal ganglion (TG) in 4–7 days, where the virus establishes latency.

Transmission of MDV occurs through the inhalation of infectious dander via the respiratory route, where the virus replication is thought to be initiated in macrophages. After 24 h of infection, cytolitic replication takes place in the lymphoid organs such as spleen, bursa and thymus, where productive cytolitic infection is initiated in the B cells, followed by the T cells. After the initial cytolitic infection associated with immunosuppression, MDV enters a latency phase in T-cells with potential integration in the telomeric regions of the host chromosomes. Finally, some of the latently-infected CD4⁺ T cells are transformed leading to the development of T-cell lymphomas in multiple organs. MDV cytolitic replication continues in the feather follicle epithelium (FFE), the only known site from where cell-free infectious virus is assembled and released into the environment.

Diagnosis

Monitoring and surveillance of AHV infections are important to recognize the distribution and occurrence conditions in the flocks. Diagnosis of AHV infections in poultry flocks are made using pathological, virological and molecular methods. Pathological diagnosis using gross pathological lesions or histopathological changes are often sufficient if the clinical symptoms and lesions are typical of the diseases associated with the AHV infections. Virological methods of diagnosis include virus isolation using cell culture, chicken embryos and animal models, as well as by the detection of viral antigens in the suspected samples. While virus isolation may not be suitable for all AHV isolates, especially as some of the virus isolates may not easily replicate in the culture systems as further adaptation is required. Serological detection of viral antigen-specific antibodies is also valuable for diagnosis of AHV infections, particularly for detection of infections at the flock levels. PCR-based molecular methods of detection of AHV-specific nucleic acids are increasingly used in the diagnosis due to their inherent speed, sensitivity, reproducibility, and because of the potential to be used on clinical samples. Real-time PCR capable of multiplexing for simultaneous detection of multiple AHV has been developed, which give quantitative data on the copy numbers of AHV isolates in clinical samples. While all of these diagnostic tools are valuable in detecting AHV in the samples, it has to be borne in mind that simple detection of viruses, nucleic acids or proteins alone in the samples does not conclusively show that the clinical disease is indeed caused by these pathogens, especially AHV species such as MDV are ubiquitous present even in clinically normal birds.

Prevention

Control strategies for diseases caused by different AHV can vary based on epidemiological features and disease characteristics although some of the basic principles are common. ILTV is controlled by coordinated efforts of rapid diagnosis, vaccination protocol, and biosecurity measures to prevent further spread. Currently, ILT control is achieved through the use of commercially available live attenuated or genetically-engineered recombinant herpesvirus of turkeys (HVT) or Fowl pox virus (FPV) vectored vaccines. Live attenuated vaccines such as the chicken embryo origin (CEO) vaccines are effective in inducing strong immunity but possess considerable residual virulence, and can cause disease, particularly when birds are stressed. Such viruses can then spread by bird-to-bird passages to initiate new outbreaks as well as causing emergence of virulent viruses. Thus, the use of attenuated vaccines has been restricted to ILTV-enzootic areas. Genetically engineered recombinant vaccines are effective to limit signs of disease, but have only limited effect on virus shedding. Thus further innovations in the design and development of new vaccines are required for more effective control of future ILTV outbreaks.

Inactivated vaccines are available against PsHV1, and are developed by using common inactivating agents. There are three main serotypes of the PsHV1 and infection of one serotype does not protect against with another serotype, suggesting the potential value of autogenous vaccines. However, development of autogenous vaccines requires time for virus isolation and vaccine production. Strict quarantine measures along with diagnostic approaches are also critical, especially for exotic pet bird breeders and companion bird keepers.

For MD, vaccination is the principal strategy for the prevention and control. MD vaccines are administered to 18-day old embryos *in ovo* or 1-day old chicks at hatch. Currently used MD vaccines include the GaHV2 strain CVI988 (Rispen), and naturally apathogenic GaHV3 strain SB-1 and HVT strain Fc126. HVT-based vaccines are also extensively used as recombinant viral vectors for protecting against multiple avian diseases. Recent studies have suggested that MD vaccines such as HVT have the potential to drive virulence because of their limited effects on MDV replication and shedding. Inactivated and attenuated vaccines available against DEV are effective in control especially when combined with quarantine measures during import and export of domestic and wild waterfowl species.

Avian Influenza Viruses (*Orthomyxoviridae*)

Nicolas Bravo-Vasquez and Stacey Schultz-Cherry, St. Jude Children's Research Hospital, Memphis, TN, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

"DIVA" (differentiating infected from vaccinated animals) Method used to differentiate influenza virus vaccinated from infected animals.

Genetic clade A taxonomic group that comprises a single common ancestor and all descendants of that ancestor.

Highly pathogenic avian influenza virus (HPAI) Designation given to select H5 and H7 avian influenza viruses that kill chickens.

Intravenous pathogenicity index (IVPI) Means of testing the level of pathogenicity of an influenza virus isolate by

observing clinical signs in infected birds over a ten-day period. Strains are considered highly pathogenic if they cause more than 75% mortality within 8 days.

Low pathogenic avian influenza virus (LPAI) Designation given to avian influenza viruses that do not kill chickens.

Reservoir A reservoir host or carrier that harbors pathogenic organisms, without injury to itself and serves as a source from which other individuals can be infected.

Spillover Term describing the spread of influenza virus into another host. Can refer to spread from wild birds into poultry.

Introduction

Avian influenza viruses (AIV) are an ongoing risk to domestic, pet, exotic (zoo) and wild birds worldwide. Disease outbreaks can threaten biodiversity by causing high morbidity and high mortality in endangered species and can also have a significant impact on a country's economy by halting trade among countries, forcing market closures and halting exportations of avian products and sub products from affected countries. While members of the class *Aves* are most susceptible to disease, a broad variety of animal species including humans can be infected with AIV leading to significant public health concerns. Indeed, at least three human influenza pandemics of the 20th century (1918, 1957 and 1968) were caused by avian-human reassorted viruses. More recently, AIV subtypes H5, H7, H9, H10, and H6 have been associated with zoonotic infections in humans resulting in a call for increased global AIV surveillance activities by the World Health Organization (WHO), Food and Agriculture Organization of the United Nations (FAO) and the World Organization for Animal Health (OIE).

Taxonomy

AIV belongs to the *Orthomyxoviridae* family, which is comprised of the following genera: *Alphainfluenzavirus* (including influenza A virus), *Betainfluenzavirus* (influenza B virus), *Gammainfluenzavirus* (influenza C virus), *Deltainfluenza virus* (influenza D virus in cattle and swine), *Thogotovirus* (a tick-borne virus), *Isavirus* and *Quarjanvirus*. As mentioned above, AIV are solely found in the *Alphainfluenzavirus*. Like all influenza viruses, they can be further classified into subtypes based on the genetic and antigenic properties of their surface glycoproteins, HA and neuraminidase (NA). Combinations of all 16 HA subtypes (H1-H16) and 9 subtypes of NA (N1-N9) have been isolated from birds. The endemic circulation of H5 viruses in many parts of the world has led to further subgrouping of the HA into unique genetic clades. A clade is a taxonomic group that comprises a single common ancestor and all descendants of that ancestor. There are geographical differences in the circulation of some HPAI H5 clades.

Virion Structure and Genome

AIV virion is pleomorphic with a size that may vary between 80 and 120 nm and may be either spherical or filamentous. The genome is composed of eight single strand negative-sense RNA segments that code for over 10 proteins including the nucleoprotein (NP), nuclear export protein (NEP) and nonstructural protein (NS), a polymerase heterotrimeric complex (polymerase basic protein 1 (PB1); polymerase basic protein 2 (PB2) and polymerase acid protein (PA)), HA, NA and matrix protein 2 (M2, ion transport channel), and the matrix protein 1 (M1) that maintains the virion shape. The virus is surrounded by a lipid envelope derived from the host plasma membrane. The trimeric HA protein has receptor (cell surface expressed sialic acid) binding activity mediating cell entry. It is the predominant surface glycoprotein being up to 80% of the total proteins present in the viral envelope. The second most predominant surface glycoprotein, the tetrameric NA, has neuraminidase activity that cleaves sialic acid molecules allowing viral egress. HA and NA must work in concert to support productive viral replication. More recently, additional accessory proteins have been identified including PB1-F2, PB2-F2, PB1-N40, PA-X and PA-N155 and PA-N182 that play crucial roles in the viral life cycle.

Life Cycle

Avian influenza viruses follow the same replication cycle as mammalian influenza viruses; attachment, entry, fusion, vRNA transport into the nucleus, transcription, replication, translation, assembly and export. If the life cycle is the same, why don't avian viruses replicate in mammalian cells and vice versa? There are several species-specific restriction factors throughout the replication cycle that block this from occurring. First, HA on the virion attaches to host cell surface expressed sialic acids (SA). The avian influenza viruses have tropism for cellular receptors with terminal $\alpha 2,3$ sialic acid (SA $\alpha 2,3$ Gal), which can be found throughout the respiratory and intestinal tract of birds and the respiratory tracts of mammals including swine, horses and humans (deep lung). Mammalian viruses bind preferentially to $\alpha 2-6$ linked SA.

Second, after attachment, AIV virions enter the cells via receptor-mediated endocytosis where the pH change within the endosome induces a conformation change in HA exposing the HA2 protein resulting in membrane fusion. While the precise pH required for the HA conformational change differs by viral strain and host species, overall HA stability has been linked to pandemic potential and ability to cross-species.

Third, after fusion, the viral ribonucleoproteins (vRNPs) are released into the cytoplasm where they co-opt host factors for transportation into the nucleus for replication initiation. Genome replication represents one of the major host range barriers between avian and mammalian influenza viruses. There are several species-specific host restriction factors that block AIV replication in mammalian cells and vice versa. These include cytoplasmic pattern recognition factors and interferon-stimulated genes (MxA, IFITM3, DDX21 as examples) and specific importin- α nuclear import proteins. Once the vRNPs have entered the nucleus, the genome is transcribed followed by replication. The AIV polymerases perform genome replication poorly in mammalian cells. This is likely due to a combination of species-specific host factors like ANP32A and DDX17 in addition to specific mutations in all three viral polymerase genes as well as in NP, NEP with PB2 E627K being the best understood. Difference in temperature at which polymerase enzymatic activity is regulated also contributes to species-specific blocks. Finally, host responses that limit virus replication may differ for avian and influenza viruses including evasion of autophagy, disruption of MAVS signaling and regulating interferon induction. Understanding the cellular and host mechanisms underlying cross-species infections will increase our ability to predicate viruses with pandemic potential.

AIV are typically propagated in the allantoic cavity of embryonated chicken eggs or in tissue culture cells including Madin-Darby canine kidney (MDCK) cells or primary chicken embryo fibroblasts (CEF) but embryonated duck and turkey eggs can also be used. While embryonated chicken eggs are the preferred option since they can support the growth of a broad range of AIV strains, many field isolates may not rapidly grow, can be contaminated with Newcastle disease virus, and HPAI AIV may be difficult to propagate to high titers in embryonated eggs given the rapid death of the embryo.

Epidemiology

AIV is highly contagious. It is spread by respiratory aerosols, bodily fluids (feces) and feathers from infected animals, contaminated fomites and environment including water. Birds play a fundamental role in the epidemiology of influenza virus. Wild bird, especially wild waterfowl (including Anseriformes) and shorebirds (including Charadriiformes), are considered the natural reservoirs for influenza virus. More than 80 different HA and NA combinations have been identified in wild waterfowl to date; much greater diversity than any other host species. These birds have the potential to spread virus between countries and even continents during migration. AIV spillover events from wild-birds to poultry can result in large outbreaks if not properly contained.

According to the FAO database, ~18,924 confirmed AIV outbreaks were reported during the current decade. The majority occurring in Asia (63%), followed by Africa (19%), Europe (15%) and the Americas (3%) (Fig. 1), primarily due to the endemic spread of HPAI H5 viruses. Since 2004, more than 18,800 HPAI H5 outbreaks have been reported in 61 countries. According to the sanitary code for terrestrial animals of the OIE, H5 and H7 AIV, regardless of pathogenicity, requires immediate notification and control measures.

In many areas of the world, live bird markets (LBM) are commonplace and part of the culture. These are also main risk factors for the spread of AIV within the market, to other areas through the movement of poultry, and for human infections. Most of the birds coming into the market are maintained in subsistence-oriented small-scale production systems commonly known as backyard production systems (BPS). BPS systems are the most common form of animal production worldwide, with domestic birds being the species that are preferably bred in this type of production system, while the production of pigs can be considered as a complementary activity. BPS animals and their products are typically consumed by their owners, transported and sold in local markets or used as gifts. Sick birds may be slaughtered, sold and consumed. Most BPS do not apply basic hygiene and biosecurity measures and the birds are often in contact with wild birds, swine and other mammals including humans. Live bird market closures have been shown to be an effective way to stop human AIV infections.

Clinical Features and Pathogenesis

Unlike humans and other mammals, influenza disease in birds is caused solely by the influenza virus A genera of the *Orthomyxoviridae* family. Disease ranges from asymptomatic to lethal depending on the viral strain and bird species. AIV may be designated as low or highly pathogenic. Historically, this was based solely on the ability of the virus to kill experimentally infected domestic chickens (intravenous pathogenicity index, IVPI). Today, this designation can be initially based on specific genetic

Fig. 1 Global avian influenza virus outbreaks reported to the FAO between 2010 and October 2018. Blue symbol = AIV outbreaks in captive animals; black circles = AIV outbreaks in domestic animals; green squares = AIV outbreaks in wildbirds; and red triangle = AIV outbreaks in humans.

signatures within the hemagglutinin (HA) protein. It is important to note that low and high pathogenicity does not refer to the disease symptoms or infectivity of the virus in humans, mammals or other species of birds.

The majority of AIV infections in wild birds are asymptomatic with the virus replicating primarily in the intestines and can be associated with shedding of high viral concentrations in the feces. Viral replication can also be found in the respiratory tract.

In domestic birds and poultry, disease can also range from a mild drop in egg production to highly pathogenic. Most avian influenza viruses cause a low pathogenic avian influenza virus infection (LPAI), where it is possible to notice respiratory symptoms (coughing, sneezing, sinus swelling and respiratory discharge), sinusitis, and respiratory tract lesions. While less severe than highly pathogenic infections (HPAI), LPAI viral infections can cause considerable losses, especially in turkeys, due to anorexia, depression and decreased egg production.

In contrast, highly pathogenic avian influenza (HPAI) virus infections are associated with severe systemic disease with variable clinical presentations, including respiratory signs, ocular and nasal discharge, cough and dyspnea, swelling of the breasts and head and necrotic combs (Fig. 2). Mortality can reach 100%. Should a bird survive a peracute infection, they may experience central nervous system involvement resulting in lack coordination, wing droop or even paralysis. Microscopic lesions may be present, though their location and severity will vary. HPAI viruses have hitherto been restricted to select H5 and H7 AIV subtypes; however, the majority of H5 and H7 AIVs are low pathogenic. HPAI variants can emerge from LPAI H5 and H7 viruses circulating in domestic poultry populations. It was thought that the primary difference between a HPAI and LPAI virus was solely based on the presence of a polybasic cleavage site in the HA allowing proteolytic processing by ubiquitous host proteases. More recent studies have shown that pathogenicity may be more complicated and involve multiple genetic changes beyond the HA.

In humans, the first example of AIV causing severe and even fatal infections in humans occurred in 1997 when 18 (6 fatal) H5N1 infections were reported in Hong Kong. AIV infections in humans can range from mild to severe and include conjunctivitis, influenza-like illness (fever, cough, sore throat, muscle aches) that can be accompanied by nausea, abdominal pain, diarrhea, and vomiting. Severe respiratory illness including shortness of breath, difficulty breathing, pneumonia, acute respiratory distress, and respiratory failure, neurologic changes and the involvement of other organ systems have also been reported. While the Asian lineage H7N9 and HPAI Asian lineage H5N1 viruses have been responsible for most human illness worldwide to date, including the most serious illnesses and highest mortality, there have been reports of humans infected with H5Nx, H9, H10, and H6 AIV subtypes. In most cases, the infected people had direct contact with infected poultry or objects contaminated by their feces and human-to-human transmission has been inefficient. The possibility that the virus could mutate or reassort and acquire the ability to transmit easily between humans is a continual concern.

Prevention

HPAI outbreaks represent a main threat to the poultry industry. As detailed in the OIE *Terrestrial Animal Health Code*, the OIE must be notified of all cases of HPAI found in any domestic or wild bird by a country's veterinary authorities. LPAI H5 and H7 AIV strains in poultry are also notifiable given their potential to mutate into highly pathogenic viruses or to infect other species.

Fig. 2 Gross lesions in chickens, ducks and geese following experimental infection with HPAI viruses. Reproduced from the OIE Scientific and Technical Review (www.oie.int) – Pantin-Jackwood, M.J., Swayne, D.E., 2009. Pathogenesis and pathobiology of avian influenza virus infection in birds. In: Mettenleiter, T., (Ed.), Avian influenza, Revue scientifique et technique (International Office of Epizootics) 28 (1), 113–136. doi:10.20506/rst.28.1.1869. (a) Oedema of comb, wattles, and periorbital tissues, A/chicken/Puebla/1994 H5N2 HPAI virus; (b) Severe subcutaneous haemorrhage and oedema of feet and leg shanks, A/Hong Kong/156/97 (H5N1); (c) Severe oedema, necrosis and haemorrhage of comb and wattles, highly pathogenic embryo derivative A/chicken/NJ/12508/86 (H5N2); (d) Thickened dermis from oedema of distal leg, A/chicken/Queretaro/14589-660/94 (H5N2); (e) Severe pulmonary oedema and haemorrhage in the lung, A/Hong Kong/156/97 (H5N1); (f) Petechial haemorrhages in epicardial fat, A/chicken/NJ/12508/86 (H5N2); (g) Submucosal haemorrhage surrounding ducts of glands in proventriculus, A/chicken/Hong Kong/156/97 (H5N1); (h) Multifocal haemorrhage in the fascial plane of the gastrocnemius muscle (pars intermedia, A/chicken/Hong Kong/220/1997 (H5N1) virus; (i) Haemorrhage in lymphoid tissue of Peyer's patches and Meckel's diverticulum of the jejunum, A/Hong Kong/220/97 (H5N1); (j) Haemorrhage in caecal tonsils and rectum, A/Hong Kong/483/97; (k) Bile-stained loose droppings from a 2-week-old Pekin duck, A/Egret/HK/757.2/02 (H5N1); (l) Two-week-old Embden goose with torticollis, A/chicken/Hong Kong/220/1997 (H5N1); (m) Mottling of the pancreas in a 2-week-old Embden goose, A/chicken/Hong Kong/220/1997 (H5N1).

Veterinary authorities within countries must establish programs to ensure early detection of AIV, response capacities and ongoing implementation of biosecurity measures to protect farms and commercial poultry. If infection is detected, a policy of culling infected and contact animals is typically followed to rapidly contain, control and eradicate the disease. The requirements for containment include:

- Humane destruction of all infected and exposed animals (following OIE animal welfare standards);
- Appropriate disposal of carcasses, litter and all animal products;
- Surveillance and tracing of potentially infected or exposed poultry;
- Strict quarantine and controls on movement of poultry and any potentially contaminated vehicles and personnel;
- Thorough cleaning and decontamination of infected premises. Due to the biochemical characteristics of AIV they are susceptible to a broad variety of disinfectants, among them sodium hypochlorite, quaternary ammonias, 60%–95% ethanol, povidone and other disinfectants. They also can be easily inactivated by medium temperatures (56–60°C for a minimum of 60 min), ionizing radiation and extreme pH either acid or basic (pH 1–3 or pH 10–14);
- A period of at least 21 days before restocking.

This may be applied at the level of the infected farm only or include farms within a short radius of the infected premise. All of this is done in conjunction with active surveillance.

Vaccination can be used to protect susceptible populations from infection. Vaccine strategies can be an effective emergency measure in an outbreak or as a routine measure in endemic areas. A decision to use vaccination must include an exit strategy detailing the conditions that must be met for vaccination to be stopped. The goal of an AIV vaccine for poultry is to reduce virus excretion if they are subsequently infected thus preventing virus circulation. There are a variety of vaccine types available for poultry including monovalent and bivalent inactivated vaccines, subunit killed vaccines, live recombinant vaccines, and DNA-based vaccines as examples. Consideration must be given to routes of administration and timing of administration, differences in host species immune responses, cost, and methods to differentiate vaccinated from infected birds. "DIVA" (differentiating infected from vaccinated animals) was one system that successfully enabled detection of field exposure in a vaccinated population resulting in eradication of LPAI H7 viruses in Italy. The basis of DIVA was use of a vaccine that contained a virus possessing the same HA, but a different NA, as the field virus allowing detection of antibodies to the NA of the field virus. For example, a vaccine containing an H7N3 virus can be used against an H7N1 field virus.

Avian Leukosis and Sarcoma Viruses (*Retroviridae*)

Karen L Beemon, Johns Hopkins University, Baltimore, MD, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Avian leukosis virus (ALV) First avian retrovirus, identified in 1908 by Ellerman and Bang, causes lymphomas by insertional activation of host proto-oncogenes.

Avian sarcoma/leukosis viruses (ASLV) Includes ALV and RSV and other avian retroviruses.

Bic Precursor to microRNA 155, discovered by ALV insertional mutagenesis in 1989; over-expressed in many human tumors.

Endogenous retroviruses (ERVs) Retroviruses that have infected germ cells and are transmitted genetically.

Insertional mutagenesis Mechanism of oncogenesis by ALV, which activates a nearby host oncogene after integration into the host genome. Myc expression is commonly induced.

LTR Long terminal repeat formed at both ends of the provirus during reverse transcription and contains U3, R, and U5 sequences.

MC29 Defective ALV containing the myc oncogene.

Myc A transcription factor that is oncogenic when its expression is dysregulated by ALV transduction or insertional mutagenesis.

Oncogene A gene that causes cancer.

Rous sarcoma virus (RSV) First transforming retrovirus, discovered in 1911 by Peyton Rous, causes rapid sarcomas. RSV carries an oncogene *src*, - see below.

Src The first oncogene to be discovered, as part of Rous Sarcoma Virus, and also the first protein tyrosine kinase to be identified.

History

Retroviruses of birds have been studied for over 110 years. Avian leukosis virus (ALV) was discovered in 1908 by Ellermann and Bang in Denmark, who transmitted erythroleukemia between chickens by cell-free filtrates. Rous sarcoma virus (RSV) was isolated by Peyton Rous in 1911 in New York and shown to transmit sarcomas through cell-free extracts from a chicken sarcoma. Rous was awarded the Nobel Prize in 1966 for showing that cancer can be transmitted by a virus; this was the beginning of tumor virology.

Numerous isolates of ALV and of related transforming viruses, which cause sarcomas and a variety of hematopoietic neoplasms, were reported in the decades that followed. Progress in understanding their nature was slow until the development of cell culture assays in the late 1950s and the use of genetic and cell biological approaches to study replication and transformation. The discovery of reverse transcriptase (RT) in RSV in 1970 by Howard Temin and of the origin and mechanism of action of viral oncogenes in the decade following led to an explosion of research activity. In addition to the genetic information of ALV needed for replication, RSV has a transduced oncogene, *src*, that enables it to induce sarcomas rapidly in vivo and to transform cells in culture. *Src* was the first retroviral oncogene to be characterized and the first tyrosine kinase to be identified. Bishop and Varmus received the Nobel Prize in 1989 for showing *src* is derived from its host. ALV-J was isolated in 1988 in England and is currently an economic problem in chicken flocks, especially in Asia.

Classification

The avian leukosis viruses comprise a single genus Alpharetrovirus, of the family *Retroviridae* and the subfamily *Orthoretrovirinae*. Although they share many structural and biological characteristics with the mammalian C-type gammaretroviruses (such as murine leukemia virus), these two groups are not closely related. All ALVs are closely related to one another, sharing considerable sequence and antigenic identity. Isolates are differentiated by subgroup (i.e., based on receptor utilization and determined by the *env* gene), as well as the presence or absence of oncogenes. Subgroups A–E and the more recently isolated subgroups J and K infect chickens. ALV-J was derived by recombination, acquiring a new *env* gene from an endogenous retroelement, EAV-HP. Subgroups F–I refer to endogenous viruses found in ring-necked pheasant (subgroup F), golden pheasant (subgroup G), Hungarian partridge (subgroup H), and Gambel's quail (subgroup I).

ALVs are endemic in flocks of domestic chickens (*Gallus gallus*) worldwide and will replicate efficiently in species closely related to the chicken such as quail, turkeys, and pheasants. Some RSV subgroups can transform mammalian cells and induce tumors in mammals, but with greatly reduced efficiency. The restriction of the virus to avian species is due to a lack of suitable receptors for most subgroups as well as to blocks to viral gene expression. The rare transformants that arise in RSV-infected mammalian cells often display rearrangements in proviral DNA that relieve this block.

A variety of cell types from gallinaceous birds (including chickens, turkeys, and quail) can be used to propagate avian retroviruses. Primary and secondary fibroblast cultures or cell lines (DF-1) are most commonly used, as well as lines derived from quail tumors (QT6). To avoid problems associated with frequent recombination, it is advisable to use cells that do not contain

related endogenous proviruses, such as cells from species other than chickens or from chickens bred to lack endogenous proviruses closely related to ALVs.

Virion Structure

Like all retroviruses, ALVs are transmitted as enveloped virions of about 100 nm diameter, derived by budding from the host cell membrane. Lipids derived from the host plasma membrane are present in the viral envelope and make up 35% of the virion weight. Within the retrovirus family, they are defined as having a C-type morphology. Small, dispersed spikes project from the surface of the virion; these are trimers of the two *env*-encoded proteins, SU (surface) and TM (transmembrane). The internal core of the virion appears in electron micrographs as a centrally located, roughly spherical structure about 30 nm in diameter. Immature virions seen during or shortly after budding have a more open, spherical core structure, substantially larger in diameter than the mature one. The core comprises about 1500 copies each of the five *gag*-encoded proteins (MA, p10, CA, NC, and protease) and about 100 copies each of *pol*-encoded reverse transcriptase and integrase. The avian retroviruses are unique in encoding the viral aspartyl protease as part of the *gag* gene; in other types of retroviruses, it is part of *pol*.

Virions of ALV have an equilibrium density in sucrose solutions of about 1.16–1.18 g/ml and a sedimentation coefficient of about 600S. They are quite labile and are readily inactivated by extremes of pH, as well as by heat or mild detergent treatments. They are somewhat radiation resistant, perhaps reflecting the recombinational repair capability provided by the dimeric genome.

Genome

The ALV genome consists of a homodimer of positive-sense, single-stranded (ss) RNA about 7500 nt in length. The genomic complexity of retroviruses was first determined for RSV by oligonucleotide fingerprinting and found to be the size of one 35S RNA subunit. Subsequently, all retroviruses were found to be diploid. The RNA of RSV was found to be about 2 kb larger than that of ALV due to the presence of the *src* oncogene. Transforming viruses, in which an oncogene has been inserted, have genomes varying in length from about 3200 nt (for UR2 virus) to about 9300 nt (for nondefective RSV). In most of these viruses, the oncogene has replaced some of the viral genes, leading to a genetically defective virus, which requires co-infection with helper ALV for replication. Oncogenes transduced by ALV from chickens include *src*, *myc*, *myb*, *erbA*, *erbB/EGFR*, *fps*, *ros*, and *jun*.

The avian retroviral genome is modified and processed by cell machinery. It contains a 5' m⁷GpppGm cap and a 3' poly (A) sequence, as well as internal m⁶A residues. The gene order of retroviruses was first established with the avian retroviruses.

ALV: 5'-*gag-pol-env*-3'

RSV: 5'-*gag-pol-env-src*-3'

The RSV primary transcript is incompletely spliced to yield an unspliced mRNA (which also serves as the viral genomic RNA) and spliced mRNAs for *env* and *src*. The negative regulator of splicing (NRS) within the *gag* gene, as well as inefficient 3' splice sites, inhibit complete splicing.

Important noncoding regions found near the end of the genome are necessary to provide signals for virus replication. These include an 18–21 base sequence (R) repeated at each end as well as unique sequences U3 (c. 250 nt) near the 3' end and U5 (c. 80 nt) near the 5' end which are duplicated in the long terminal repeat (LTR) during reverse transcription. The LTR contains sequences controlling transcription initiation (enhancers and promoters) and polyadenylation. Adjacent to these are the sites for initiation of reverse transcription: the primer binding (PB) sequence next to U5. Between PB and the beginning of *gag* is an approximately 300 nt leader region, which contains signals important for the dimerization and packaging of the genome into virions. There are also three short open reading frames in this region upstream of *gag*.

The direct repeat (DR) sequences flanking the *src* gene in RSV are necessary for cytoplasmic accumulation of full-length viral RNA. ALV has one copy of the DR sequence, which is involved in export of the RNA from the nucleus to the cytoplasm, with the help of cellular proteins NXF1 and Dbp5. Further, an RNA stability element (RSE) downstream of the Gag termination codon inhibits nonsense-mediated decay of the ALV genome. The RSE binds PTBP1 and inhibits binding of UPF1 to the terminating ribosome complex.

The ALV genome encodes nine proteins, the products of three genes. The Gag proteins constitute the major structural components and are sufficient to form virus-like particles. The Gag-Pro precursor is processed during release of virus into four Gag proteins: MA (matrix, 19 kDa) which interacts with the cell membrane; p10, a 10 kDa protein; CA (capsid, 27 kDa) which forms the core shell structure; and NC (nucleocapsid, 12 kDa), an RNA-binding protein necessary for specific encapsidation of genomic RNA. The Gag-Pro precursor also contains the 15 kDa PR (protease) peptide necessary for processing all internal virion proteins. The Pol reading frame is expressed as a fusion protein with Gag and Pro, processed to yield RT (usually present as a heterodimer of 98 and 66 kDa reflecting partial processing by PR), and integrase (IN, about 32 kDa); these are the two enzymatic components necessary for synthesis and integration of the DNA provirus. The *env* gene encodes the Env precursor (Pr95) which is processed as a membrane protein and cleaved by host cell proteases to yield the SU and TM glycoproteins. SU has an apparent molecular weight of about 85 kDa, about half of which is due to the presence of approximately 14 N-linked carbohydrate side chains. The TM

glycoprotein has an apparent molecular weight of about 37 kDa. The SU and TM products remain as a disulfide-bonded heterodimer with SU containing the activity necessary for receptor binding and TM mediating fusion with the cellular membrane.

Life Cycle

Replication of avian retroviruses requires reverse transcription of the RNA genome to DNA and its integration into the host genome. This group of viruses provided some of the important early models for studying these processes. Howard Temin proposed and demonstrated reverse transcription of RSV RNA by a virus-encoded enzyme and received the Nobel Prize in 1975 for this work. The viral integrase protein is necessary for cleavage of the host genome and insertion of the provirus. The cellular FACT protein complex facilitates this process for the avian viruses. The ALV proviruses show fairly random integration sites with a slight preference for transcription start sites in tissue culture. However, in tumors there is a strong selection for integration near oncogenes, and the ALV regulatory sequences drive expression of the cellular oncogenes.

Entry of the virion into the cell follows interaction with a specific receptor on the cell surface. Viral subgroups (A–J) have been identified on the basis of distinct receptor recognition. The presence of receptors for specific subgroups is polymorphic among birds. Four unlinked genetic loci (Tv-a, Tv-b, Tv-c, and TV-j) for ALV receptors have been genetically identified in chickens. The dominance of susceptibility over resistance alleles at each of these loci implies that they encode the receptor directly. The Tv-b locus has several alleles, controlling susceptibility to subgroups B, D, and E. Receptors for ASLV subgroups A, B, C, D, E, and J have been identified. The Tv-a receptor resembles a portion of the receptor for low-density lipoprotein and is unrelated to other known retroviral receptors. The receptors for B, D, and E are all in the tumor necrosis factor receptor family. The ALV-C receptor is in the butyrophilin family and consists of two immunoglobulin-like domains. ALV-J uses the Na⁺/H⁺ exchanger 1 as its receptor. The newly isolated ALV-K shares the Tv-a receptor with subgroup A viruses. Entry of the virion core into the cell is by fusion of viral and cellular membranes, which is mediated by the viral glycoproteins.

Once within the cytoplasm of the infected cell, reverse transcription within the permeabilized core structure copies the ssRNA genome into double-stranded DNA. This process – which varies little from that of other retroviruses – includes a series of ‘jumps’ from one end of the template to the other. The DNA product is longer than the genomic RNA template and has generated a long terminal repeat (LTR) at both ends. The LTR contains sequences necessary for DNA integration and for synthesis and processing of viral RNA. Like other retroviruses, ALVs exhibit very high rates of homologous recombination – a consequence of the diploid genome and the ‘jumping’ mechanism of reverse transcription. The latter also permits relatively high rates of nonhomologous recombination, leading to frequent rearrangements of the genome as well as the occasional acquisition of foreign sequences such as oncogenes.

Integration of viral DNA into fairly random sites in the cell genome is accomplished by the IN protein which has entered the cell with the virion and remains associated with the DNA. The cellular FACT protein complex interacts with ALV IN and promotes integration. The process of integration leads to the insertion of the linear viral DNA into cell DNA. Integrated ALV DNA is characterized by the loss of two bases from each end of the viral LTR sequence and the duplication of six bases of the cell DNA target sequence at the integration site.

RNA transcription of the provirus is mediated by cellular RNA polymerase II, directed to the correct initiation site by promoter and enhancer sequences in the LTR. The strength of the enhancer elements is a major factor distinguishing pathogenic from nonpathogenic (RAV-0) ALV isolates. Unlike the more complex retroviruses, there is no apparent role of virus-encoded proteins in regulating the transcription process. Processing of the viral transcripts includes addition of poly(A) following a canonical signal (AAUAAA) in the RNA derived from the 3′ LTR and splicing of the fraction of the transcripts destined to become mRNA for the *env* and *src* genes. Splicing removes most of the *gag*, *pro*, and *pol* sequences. Importantly, a fraction of the primary unspliced RNA transcript serves as genomic RNA and as the mRNA for Gag and Pol polyproteins.

Translation of the full-length mRNA leads to two products: The Gag precursor of 76 kDa and the Gag-Pol precursor of 180 kDa. Synthesis of the latter polyprotein is made possible by a –1 translational frameshift about 5% of the time, reading through the termination codon at the end of Gag. Assembly of the precursors appears to be at the cell surface and is coincident with budding. Release of the immature particle (characterized by a hollow, symmetrical core which almost fills the virion) is rapidly followed by cleavage of the Gag and Gag-Pol precursors. This cleavage is accompanied by condensation of the core into its mature form. Since the PR protein embedded in the Gag precursor contains only one-half of the active site, dimerization of this domain is necessary for cleavage to occur. This requirement probably helps to delay cleavage until the appropriate time after budding.

Once infected, the host cell is usually not killed by virus replication. A strong superinfection resistance due to blockage or loss of viral receptors develops soon after infection and prevents accumulation of proviruses by reinfection. In some cases, weak or slow development of superinfection resistance is associated with a cytopathic interaction of the virus with its host cell.

Epidemiology

ALV's have been a major cause of death in poultry, mainly by induction of leukoses in hematopoietic cells. ALV spreads by both vertical and horizontal transmission and is controlled mainly by eradication of breeding stock containing ALV. ALV's subgroup A and B were the predominant subgroups in the 20th century and shown to cause B cell lymphomas, originating in the bursa of Fabricius and metastasizing to other organs. They were largely brought under control in the late 20th century.

However, a new subgroup of ALV (subgroup J), causing myeloid tumors, was isolated from meat-type (broiler) chickens in 1988 in England. Similar viruses were isolated from broiler chickens in the US and China. By 2004 ALV-J infection had spread to layer chickens in China, causing hemangiomas and other diseases, as well as reduced egg laying. It has since become a major economic problem in Asia. Their pathogenicity is evolving rapidly with a change in host range and tumor types. The layer chicken isolates have incurred genetic changes in the 3' UTR and *env* gene.

ALVs are endemic in flocks of domestic chickens (*Gallus gallus*) worldwide and will replicate efficiently in species closely related to the chicken such as quail, turkeys, and pheasants. Some RSV subgroups can transform mammalian cells and induce tumors in mammals, but with greatly reduced efficiency. The restriction of the virus to avian species is due to a lack of suitable receptors for most subgroups as well as to blocks to viral gene expression. The rare transformants that arise in RSV-infected mammalian cells often display rearrangements in proviral DNA that relieve this block.

A variety of cell types from gallinaceous birds (including chickens, turkeys, and quail) can be used to propagate avian retroviruses. Primary and secondary fibroblast cultures or cell lines (DF-1) are most commonly used, as well as lines derived from quail tumors (QT6). To avoid problems associated with frequent recombination, it is advisable to use cells that do not contain related endogenous proviruses, such as cells from species other than chickens or from chickens bred to lack endogenous proviruses closely related to ALVs.

Transmission of virus is principally vertical by infection of the offspring through virus secreted into the egg. Indeed, high titers of ALV are often detectable in commercial hen's eggs. Horizontal spread of virus is naturally much rarer, requiring close contact, but virus can be readily spread from infected birds via contaminated needles during vaccination or through vaccines prepared from infected eggs or cell cultures. All isolates of ALV replicate efficiently in fibroblast cultures and in the bursa. Tropism for other tissues varies among isolates and is determined by both *env* and LTR sequences.

Clinical Features

ALV's of subgroup A and B cause B-cell lymphomas and other neoplasms. The B cell lymphomas originate in the bursa of Fabricius and metastasize to liver, spleen, and kidneys. They cause death in a few months. In contrast, ALV-J causes predominantly myeloid tumors and hemangiomas. Egg production was drastically reduced. Immunosuppression and weight loss also occurred.

ALV's with transduced oncogenes cause a variety of more rapidly occurring (acute) cancers, including sarcoma, myeloblastosis, and erythroblastosis by over-expression of mutated oncogenes from the viral LTRs.

Pathogenesis

ALVs induce a wide spectrum of disease in naturally or experimentally infected animals. The prototypic disease induced by ALV is a B-cell lymphoma arising in the bursa of Fabricius starting a few months after infection and spreading to the liver and other organs during its course. Other malignancies, including myeloid tumors, erythroleukemia, sarcoma, and others, are not uncommon depending on the strain of virus and bird and the time and route of inoculation. The malignant diseases induced by viruses, which do not contain oncogenes, are the consequence of insertional activation of cellular proto-oncogenes (such as *myc* in the case of lymphoma, *erb-B* in erythroleukemia, etc.). This process is termed promoter insertion or insertional mutagenesis and was first observed by Bill Hayward with ALV integrations in *myc*. Additional integrations into the noncoding *bic* gene were observed in 1989. *Bic* was subsequently found to be the precursor of miR-155. When viruses infect 10–14-day embryos, more rapid lymphoma induction is observed with frequent integrations into *myb* and an antisense long noncoding RNA in the TERT promoter. In addition to malignancies, these viruses also induce hemangiomas, osteopetrosis, and wasting diseases. In some cases, an immune response against infected cells may be important; in others, cytopathic effects may play a significant role.

A unique characteristic of ALV and a few other retroviruses is their ability to incorporate host sequences into their genome and to alter the function of proto-oncogenes to generate oncogenes. The presence of an oncogene renders the virus capable of inducing malignant transformation of cells in culture and one of a variety of malignant and rapidly fatal diseases in birds. At least 20 distinct cell sequences have been incorporated by ALV into a number of distinct isolates. RSV, which contains *src*, is the prototype oncogene-containing virus. Other notable oncogene-containing ALV variants include avian myeloblastosis virus (AMV; containing *myb*); avian myelocytomatosis virus-29 (MC-29; *myc*); avian erythroblastosis virus (AEV; *erb-A* and *erb-B*); Fujinami sarcoma virus (FSV; *fps*); and University of Rochester sarcoma virus-2 (RU-2; *ros*). Study of the genetic alterations that distinguish these oncogenes from proto-oncogenes, and the enzymatic and physiological function of the proteins they encode has been an important part of modern cancer research. Incorporation of oncogenes into the virus genome is usually at the expense of some viral genes and co-infection of a cell with a wild-type (helper) ALV is necessary to provide viral proteins for replication of oncogene-containing viruses. RSV, which exists as a replication-competent transforming virus, is the exception. It should be noted that the oncogene-containing viruses are not efficiently transmitted from one animal to another due to their rapid pathogenicity. In most cases, they have probably arisen in the animal from which they were isolated and would have died out if not brought into the laboratory. Not all members of this group are highly pathogenic. RAV-0 (an endogenous virus) can infect susceptible chickens and induce viremia, but disease is rare and occurs only after a long latent period. The reduced virulence is probably an important feature of viruses inherited in the germline.

In infected birds, the only significant immune response is the appearance of type-specific neutralizing antibodies, which apparently recognize the regions of Env involved in receptor recognition. Group specific responses against Env or other proteins are not usually observed in infected chickens, although inoculation of virus into mammals induces antibodies capable of recognizing all virion proteins in the absence of subgroup-specific reactivity. The limited immune response observed in infected chickens has been attributed to the presence of endogenous proviruses whose expression (even at a low level) can induce tolerance to antigens in common with infecting virus. Indeed, it has been suggested that induction of tolerance might be a desirable feature for the animal, since it could prevent or limit immunopathological sequelae of infection. Postinfection immune response seems to be of little consequence in preventing subsequent malignant disease, since the cells, which will eventually form the tumor, are probably infected quite soon after infection, and the long latency reflects the necessity for subsequent rare events (such as mutations in other genes) rather than a continuing period of virus replication.

Diagnosis

Avian retroviruses can be detected by ELISA assays or PCR assays.

Treatment

Control of ALV infection is generally by detection and culling of infected individuals. No useful vaccination strategy has been developed. In principle, it should be possible to virtually eliminate the disease by breeding appropriate receptor alleles into commercial strains.

Lymphoid leukosis caused by ALV (subgroups A and B) was eradicated in primary breeders in the US in the 1980s and 1990s, reducing the disease incidence in commercial layer hens. However, commercial broiler and layer chickens are still struggling with ALV-J and ALV-K infection in many countries, especially in Asia.

Endogenous Retroviruses

ALV's can become established in the germline and inherited stably as endogenous retroviruses (ERVs). Naturally occurring endogenous alpha proviruses form a distinct lineage of ALVs, showing a specific host range (subgroup E) for which many domestic chickens lack receptors (a phenomenon known as xenotropism), and a reduced replication capacity and pathogenicity relative to exogenous viruses. Endogenous viruses are usually expressed at a very low level and are usually defective in sequence.

Analysis of the sequenced chicken genome revealed many endogenous retroviruses related to the gamma and beta retroviruses, with fewer alpha retroviruses. There were also proviral intermediates between alpha and beta genera. About 20% of these ERVs were transcribed and associated with ribosomes. In addition, there were thousands of solo LTRs.

Introduction

Bluetongue virus (BTV) infects a wide range of ruminants, including both domestic (sheep, cattle, goat, water buffaloes, camels etc.) and wild animals (white-tailed deer, elk, blesbuck etc.) and is common throughout the world, periodically causing serious outbreaks, particularly in sheep and cattle. BTV is transmitted by blood sucking biting midges (gnats) of the genus *Culicoides*.

Bluetongue disease in sheep and cattle was first described in the late 18th century, but was recorded only in the late 19th century by Hutcheon, the Chief Veterinary officer of Cape Colony in South Africa. The clinical features were officially reported in 1902 as ‘malarial catarrhal fever’ of animals. However, since the diseased sheep generally exhibited distinctive lesions in their mouths and on the tongue, with the latter often turning blue, Spreull suggested the use of the common name ‘bluetongue’. In addition to this, Spreull also discovered that the causative agent was filterable and transmissible to cattle and goats causing subclinical infection.

The disease was confined to Africa until 1943 when the first recognized outbreak outside of Africa occurred in Cyprus and soon after, in surrounding countries. Similar outbreaks were also observed in the USA around the same period and virus was isolated from one such outbreak in California in 1952. The disease then spread into southwest Europe and the Indian subcontinent causing severe outbreaks. Over the years, many serotypes of the virus have been isolated from all over the world including Australia, Central and South America and the Caribbean. In recent years, BTV has caused infections in most countries in central and southern Europe and has spread as far north as the United Kingdom and Denmark.

Due to its serious economic importance, BTV has been studied extensively and substantial progress has been made in characterizing the virus at the atomic, molecular, and genetic levels. BTV classification, three-dimensional structure, genetics and the virus replication cycle are summarized here along with epidemiology, pathogenesis and diagnosis, as well as vaccination strategies.

Classification

BTV is the prototype of the orbivirus genus, the largest of the genera within the *Reoviridae* family. Currently, 22 distinct virus species have been classified under the orbivirus genus. Orbiviruses are insect-borne viruses capable of infecting a wide range of hosts, including humans, animals, plants, and insects. Despite basic similarities, orbiviruses differ greatly in their structure, physicochemical properties, replication cycle, pathogenesis, and epidemiology. BTV includes 28 distinct serotypes identified worldwide, including novel isolates of atypical BTV, all of which can be genetically traced to a singular geographic origin.

Virion Structure and Genome

BTV is the most extensively studied virus among the Orbiviruses. The particle has a diameter of 86 nm, and consists of two capsids of concentric protein layers, comprising seven structural proteins and a genome of 10 dsRNA segments. The outer capsid is made up of two proteins, VP2 and VP5, which surround the inner capsid, termed “core”. The core is composed of VP7 and VP3 in two concentric layers, encapsidating the dsRNA genome and the viral replicase complex of three minor proteins, VP1, VP4, and VP6.

The complete genome of BTV-10 was the first sequenced in its entirety in 1989 and was the largest reported complete genome sequence of an RNA virus at the time. The total length of BTV-10 genome was determined to be 19,218 base pairs, with each segment varying in length, from 3954 bp to 822 bp. Based on the size differences, the RNA segments were numbered as S1-S10 and grouped into three size classes, large (S1-S3), medium (S4-S6) and small (S7-S10). All 10 RNA segments share unique 5' and 3' complementary ends and lack a 3' poly-A tail. Segments 1–8 each have only a single open reading frame, encoding six of the seven structural proteins (VP1-VP5 and VP7) as well as two non-structural proteins (NS1 and NS2). The two smallest segments, S9 and S10, have overlapping ORFs, S9 encodes the smallest BTV structural protein, VP6, and a small non-structural protein, NS4 encoded in the +1-reading frame, while S10, encodes the two isoforms of the non-structural protein NS3, namely NS3 and NS3A, with the latter lacking the N-terminal 13 amino acid residues (Table 1). A recent report suggests that S10 may also encode an additional NS protein, NS5, with unknown function.

Mature BTV particles are relatively fragile, unlike for example, reovirus and rotavirus particles, and therefore pose a challenge to purify intact virion particles from infected cells. The initial transmission electron micrographs (TEM) of BTV suggested a double-shelled arrangement of the virion particle. A low resolution (5 nm) cryo-electron microscopy (cryoEM) reconstruction of the virion particles and recombinant virus-like particles (VLPs) formed by the co-expression of four major capsid proteins (VP2, VP3, VP5 and VP7) revealed that the particles have distinct icosahedral morphology. The analysis also showed the specific arrangement of

Table 1 Proteins encoded by BTV segments and their functions

Genome segment	No. of bp ^a	Proteins	No. of aa	Predicted size (Dalton)	Estimated no. of molecules	Location in virion	Function
S1	3954	VP1	1302	149,588	12	Inner core	RNA dependent RNA polymerase
S2	2926	VP2	956	111,112	180	Outer capsid	Receptor binding, virus entry, hemagglutinin, type specific neutralization
S3	2772	VP3	901	103,344	120	Core	Scaffold for VP7 trimers
S4	2011	VP4	654	76,433	~24	Inner core	Capping enzyme with guanylyltransferase, methyltransferases 1 and 2, RNA 5' triphosphatase, inorganic pyrophosphatase NTPase activity
S5	1639	VP5	526	59,163	360	Outer capsid	Membrane penetration, virus entry
S6	1770	NS1	552	64,445	NA	Non Structural	Upregulates viral protein translation, forms tubules
S7	1156	VP7	349	38,548	780	Core surface layer	Viral core protein, group-specific antigenic determinant
S8	1123	NS2	357	40,999	NA	Non Structural	Phosphorylated, recruits viral ssRNA and core components, forms cytoplasmic VIBs, site of viral core assembly
S9	1046	VP6	328	35,750	60–72	Inner core	Involved in viral genomic RNA packaging, has hexameric configuration, helicase
S10	822	NS4	~79	~10,000	NA	Non Structural	Host-virus interaction, regulates interferon response
		NS3	229	25,572	NA/Low level	Non Structural	Glycoprotein, responsible for virus trafficking and egress
		NS3A	216	24,020			

^aBased on BTV 10 genome sequence.

the two outer capsid proteins (VP2 and VP5) for the first time, one with 120 globular densities and the other with 60 spike-like triskelion structures. It was proposed that trimers of VP2 form the triskelion motifs while the globular configurations were the VP5 trimers. With further advancements in cryoEM data acquisition, density reconstitution, and image reconstruction, the structure of the virion particle was further refined to ~24 Å and subsequently to 7 Å. These studies confirmed that the sail-like spikes of triskelion motifs are VP2 (111 kDa) trimers and the globular densities are VP5 (~59 kDa) trimers. The surface of the core forms a middle layer with 260 VP7 (~38 kDa) trimers and an inner layer formed by 60 VP3 (~103 kDa) dimers (detailed below). A recent 3.5 Å structure of BTV further revealed the secondary structural features of VP2 and VP5, and the specific sites of interaction between these two proteins and the scaffolding inner core, at atomic resolution (Fig. 1). Structurally each VP2 monomer (120 in total) is divided into four distinct domains, a hub, a hairpin, a pyramid-shaped body, and a highly flexible external tip. The exposed nature of this domain is consistent with its role as a key determinant of the host antibody response. The hub domain contains a lectin-like β -barrel flanked by helices that drive the trimerization of three monomers such that they sit above the VP7 layer of the core surface. A typical zinc-finger motif, CCCH, with tetrahedral coordination is located at the interface of the hub and the body domains. Each of the 120 VP5 trimers forms a compact globular structure. Each monomer (360 in total) forms a rectangular shaped structure with three distinct domains, an N-terminal flexible dagger sequestered in the canyons underlying the core surface, a helix-rich unfurling domain with a central coiled-coil motif that facilitates trimerization (analogous to a viral fusion protein), and an anchoring domain in the C-terminal region. This domain possesses four antiparallel β -strands with a potential membrane-binding motif. The VP5 trimers surround the VP2 trimers, underlying the gaps in the triskelion arms of VP2 such that the hairpin and hub domains of VP2 are in contact with the unfurling and membrane associating motifs of VP5.

The core (~470 S), unlike the virion particle, is highly robust and was the first particle of BTV analyzed by cryoEM in 1992. The 75 nm structure revealed a T = 13 icosahedral lattice and the presence of concentric layers of VP7, forming the core surface and VP3, forming the inner layer (subcore). The X-ray crystal structure of recombinant VP7 revealed an unusual organization of VP7 trimers, which provided a paradigm in the field and enabled the initial characterization of the assembly of the VP7 layer onto the VP3 layer at 23 Å resolution by cryoEM. These analyses further facilitated solving the subsequent X-ray crystal structure of the core at ~3.5 Å resolution (Fig. 1). The surface of the core is made up of 780 copies of the VP7 monomer arranged as 260 trimers with a T = 13 icosahedral lattice arranged around 132 channels as six-membered rings, with five-member rings at the vertices. In the T13 lattice, VP7 trimers occur as pairs of five quasi-equivalent trimers with each trimer containing two distinct domains, an upper β -rich domain, exposed in the core surface, making extensive contacts with the outer capsid and a helical lower domain that interacts with the VP3 layer below. The underlying subcore layer is composed of 60 VP3 dimers arranged as 12 decamers on a T = 2 symmetry. The VP3 dimers are made up of two nearly identical isoforms (A & B) with a unique plate-like structure resembling a triangular wedge consisting of apical, carapace and dimerization domains. Each VP3 decamer consists of five 'A' molecules arranged around a five-fold apex with a central pore and five 'B' molecules arranged around 'A'. In addition to the pores at the five-fold axes, there are pores at the three-fold axes that are blocked by VP7 trimers in the intact core. VP7 trimers in the core additionally make contact with the tip and hub domains of the VP2 spikes and extensively with all three VP5 domains with the VP5 domains bridging the channel formed by six VP7 trimers in the core. The VP3 layer has been suggested to be in contact with the enclosed viral dsRNA genome.

(C) and (D) X-ray crystal structure of BTV core particles showing (C) 260 VP7 trimers arranged as five quasi-equivalent trimers in $T = 13$ icosahedral symmetry (colored in red, orange, green, yellow and blue), (D) VP3 scaffold showing the unique A (green) and B (red) isoforms and highlighting VP3 decamer (dashed ellipse). Adapted from: (A) and (B) Zhang, X., Patel, A., Celma, C.C.P., *et al.*, 2016. Atomic model of a nonenveloped virus reveals pH sensors for a coordinated process of cell entry. *Nature Structure Molecular Biology* 23, 74–80. (C) and (D) Grimes, J.M., Burroughs, J.N., Gouet, P., *et al.*, 1998. The atomic structure of the bluetongue virus core. *Nature* 395 (6701), 470–478.

While these studies provided detailed structural descriptions of the VP7 and VP3 layers, the exact positioning of the three minor proteins and the dsRNA genome within the core remains unclear. However, X-ray diffraction patterns of the BTV cores suggest that most of the genomic dsRNA is packed as well-ordered layers surrounding putative transcription complexes at the apices of the core particle. Further, cryoEM reconstruction of recombinant core-like particles (CLPs) of VP3 and VP7 along with two minor proteins, VP1 (polymerase) and VP4 (capping), revealed a flower-shaped density at the 5-fold axes underneath the VP3 layer.

Life Cycle

In both mammalian and insect cells, BTV follows the typical steps of virus replication, which begin with virus entry and release of intact viral cores, followed by synthesis of viral ssRNA, translation of the viral proteins, amplification of the viral genome, assembly of nascent virus particles and, finally, egress (Fig. 2).

Virus Attachment and Entry Into Cells

In mammalian cells, BTV infection is initiated by attachment of the virus to the cell surface by the outer capsid protein, VP2, primarily via the tip domain that protrudes from the surface of the particle. While the identity of the receptor and the exact mechanism of cell entry have not been elucidated, it has been reported that sialoglycoproteins and sialic acids play roles in the virus entry process. BTV primarily uses the endocytic pathway and is transported to the cytoplasm via clathrin-coated vesicles. Once internalized, the clathrin coat is released and the endocytic vesicle fuses with an early endosome. The CCCH zinc-finger motif in VP2 acts as a pH sensor in the early endosome, triggering a conformational change, and the eventual disengagement of VP2 from the virus particle. The particle lacking VP2 is then transported to the late endosomal compartment, where a histidine cluster – located at the interface of the anchoring domain and the helices of the unfurling domain of VP5 – senses the late-endosomal pH. This triggers the release of

Fig. 2 Overview of BTV replication cycle. Virus entry occurs via sialic acid attachment by VP2 followed by clathrin-mediated endocytosis. VP2 senses the pH in the early endosome leading to its detachment. The core particle with exposed VP5 layer then moves to late endosome where VP5 senses the acidic pH leading to a conformational change and membrane permeabilization. Core is then released into the cytosol. Transcription and translation of viral proteins occurs leading to formation of tubules (NS1) and viral inclusion body (NS2) where components for core assembly are concentrated. Assembled core particles leave the VIB, leading to maturation by addition of the outer capsid proteins VP5 and VP2. The particles are trafficked using exocytic vesicles mediated by NS3 interaction with host factors leading to egress via budding or via host cell lysis.

the putative membrane-interaction element leading to the dramatic refolding of the dagger domain and the helical unfurling domain to form a new filamentous barb-like structure that protrudes out while the anchoring domain remains attached to the VP7 layer below. It is likely that the filamentous structures interact with the endosomal membrane and initiate permeabilization and destabilization of the endosomal vesicles, facilitating the release of the highly stable core, containing the dsRNA genome and the viral replication complex, into the host cytoplasm.

Transcription and Replication

Once released into the host cytoplasm the transcriptionally active core remains intact and initiates replication of the viral genome. Single-stranded RNAs (ssRNAs) from the 10 genomic segments are repeatedly transcribed by the enzymes within the core and released into the host cell cytoplasm through the channels that connect the interior of the core with the exterior. The released transcripts (mRNAs) are capped at the 5'-end but lack the canonical 3'-poly-A, and can serve as templates for both translation and for negative-strand RNA synthesis to form new genomic dsRNA segments.

The advent of a BTV reverse genetics (RG) system has enabled the dissection of genome replication within mammalian cells, which was found to occur in two stages. In the first, newly synthesized transcripts initiate the primary replication cycle by generating the primary replicase complex (PRC) consisting of the enzymatic minor proteins, VP1, VP4, and VP6, the inner core protein VP3, as well as two non-structural proteins, NS1 and NS2. NS1 is required for viral protein synthesis, whilst NS2 plays an essential role in selectively recruiting the four subcore proteins and the ssRNAs during particle formation (discussed below). In the second step, 10 ssRNAs segments are recruited to the PRC, forming the subcore. The viral replicase complex, composed of VP1, VP4, and VP6, then replicates the viral ssRNA to form dsRNA.

VP1 (150 kDa) is the largest of the BTV proteins and has shown RNA dependent RNA polymerase activity in vitro. Recombinant VP1 is capable of *de novo* dsRNA synthesis when supplied with BTV or Rotavirus mRNAs. However, it cannot synthesize dsRNAs from non-viral RNAs unless they are fused with BTV specific 5' and 3' sequences, suggesting that the recognition of a specific sequence or secondary structure element is essential for the initiation of RNA replication. No high-resolution structures are available for VP1. However, molecular modeling of the sequence based on the known Reovirus λ 3 structure, suggests that VP1 has the typical RdRp organization with an N-terminal domain, a central polymerase domain, and a C-terminal domain.

VP1 lacks the ability to cap the dsRNAs produced. This activity is instead performed by VP4. VP4 (76 kDa) functions as a single capping protein and contains all the necessary domains to catalyze the reactions required to generate type-1-like cap structures on ssRNAs in vitro, similar to those found on BTV mRNAs. VP4 was the first capping enzyme within the *Reoviridae* family to have its structure solved by X-ray crystallography. This revealed a unique multi-domain structure with an hourglass morphology with defined domains arranged in a linear layout (Fig. 3). While the atomic structure of VP4 did not account for its RNA-triphosphatase function, it provided the molecular basis for its guanylyltransferase and two methyltransferase activities (guanine-N7-methyltransferase, N7MTase and nucleoside-2-O-methyltransferase, 2'OMTase) activities characterized by in vitro experiments previously.

Fig. 3 Structure of BTV VP4 and NS1. (A) X-ray crystal structure of VP4 showing its domain organization. (B) Cryo-EM density reconstruction of NS1 tubule structure. (C) Atomic model of NS1 monomer showing the different domains.

VP6 (36 kDa) is the smallest of the proteins in the replication complex. *In vitro* analysis of recombinant VP6 suggests that it possesses helicase and nucleotide triphosphatase (NTase) activities and has high affinity for both ssRNAs and dsRNAs. Recent studies have shown that VP6 is essential for viral RNA replication and genome packaging. This attribute of VP6 has been utilized in the development of new replication defective vaccine strains, named 'ECRA' (Entry Competent Replication Abortive) vaccines (discussed below). Sedimentation analysis, size exclusion chromatography and EM analysis suggest that the VP6 forms hexamers with ring-like structures similar to those observed for other DNA and RNA helicases. While the VP6 structure is yet to be fully characterized, Nuclear Magnetic Resonance (NMR) analysis in 2014 suggested the presence of two large dynamic loops.

In tissue culture, the first BTV-specific proteins are detectable 2 h post infection and the rate of protein synthesis increases rapidly until 12–13 h post infection, after which it slows but continues until cell death. The two NS proteins, NS1 (64 kDa) and NS2 (41 kDa), involved in primary replication cycle, are synthesized abundantly early in BTV infection forming two virus-specific intracellular structures, tubules, and viral inclusion bodies (VIBs), respectively. These two structures are the hallmarks of BTV infection. By contrast, synthesis of NS3 and NS3A (26 and 25 kDa) varies from barely detectable to highly expressed, depending on the host cells.

NS1 has been suggested to positively influence the expression of BTV proteins and initial cryoEM analysis suggested that its tubules are made up of helically coiled NS1 dimers. Near-atomic resolution structure of two NS1 tubular forms has recently been obtained by cryoEM and the structure revealed that the same NS1 monomer gives rise to tubules with different helical assemblies and varying diameter (500 Å to 580 Å). Each NS1 monomer structure consists of an N-terminal foot domain, a head domain, and a body domain connected to an extended C-terminal arm (Fig. 3). The C-terminal arm of an NS1 subunit wraps above the head domain of another NS1 subunit through hydrophobic interactions in the tubular form and deletion of this C-terminal arm perturbs tubule formation. It does not, however, inhibit virus recovery and NS1 is still functional, indicating that NS1 tubules are not necessary for mRNA translation. The structure also revealed the presence of two metal-bound zinc-finger motifs in the NS1 monomers. Biological analysis confirmed that while both are needed for tubule assembly, only one is involved in the regulatory function of NS1 during replication.

NS2 is a phosphoprotein and is synthesized abundantly throughout infection. Initially distributed throughout the cytoplasm of infected cells, NS2 rapidly accumulates to form dense globular structures, known as virus assembly factories or virus inclusion bodies (VIBs). NS2 has a strong affinity for ssRNAs and viral ssRNAs accumulate within the VIBs soon after their formation. NS2 is phosphorylated at serine 249 and serine 259 by casein kinase II (CKII) and mutations of either one or both the serine residues influence VIB morphology. More recently, it has been shown that protein phosphatase 2A dephosphorylates NS2 and along with CKII modulates the phosphorylation status of NS2 in infected cells thereby regulating VIB morphology and virus replication. The N-terminal region of NS2 (160aa) was shown to have a β -sandwich motif in its monomeric form and forms homo-multimers composed of 10–11 monomers. The VIBs are the site of virus assembly and act as a scaffold for subcore formation. They contain viral RNAs in abundance along with the other viral proteins required for genome packaging, replication, and core assembly. Upon formation of the subcore in the VIBs, VP7 is added onto the VP3 layer to form the stable mature core particle.

The viral core is then released into the cytoplasm, where the outer capsid proteins (VP2 and VP5) are layered on to the core surface. The mature progeny virions are then released from the host cell. NS3/NS3A, which is the only glycosylated transmembrane protein of BTV, traffics through the endoplasmic reticulum and Golgi apparatus, and is involved in virus budding at the plasma membrane (discussed below), while the smallest protein, NS4 (77–79 residues), acts as an interferon antagonist and appears to be a virulence factor in sheep.

Core Assembly

NS2 plays a major role in recruiting each of the core components including the ssRNA transcript to facilitate the entire core assembly process within the VIBs. However, since core-like and subcore-like particles can be assembled *in vitro* by expressing the recombinant structural proteins, it has been possible to define the assembly pathway of VP3, from dimer to VP3 layer via the decamer intermediates and to show how 260 pre-formed VP7 trimers are layered onto the VP3 subcore. Recombinant core assembly data has further been supported by an *in vitro* cell-free assembly (CFA) system, which provided additional insights into

the entire core assembly process. In this assay, in vitro translated VP1, VP4, and VP6 were initially incubated with the ten ssRNA transcripts, followed by sequential addition of VP3 and VP7 to reconstitute a subcore and core structures with all ten ssRNA segments. The subcores were sensitive to RNase treatment prior to addition of VP7, suggesting that VP7 stabilizes the core. Furthermore, the assay also revealed an essential role for VP6 in genome packaging. In the presence of triphosphates the packaged ssRNA could serve as template for dsRNAs synthesis. Most importantly, in vitro reconstituted core particles were infectious in BTV permissive cells. Thus, NS2 was dispensable for core assembly in vitro suggesting its role in vivo is passive, acting as a condenser of the necessary components required for assembly.

Assembly of Genomic RNA and Packaging

The mechanism by which BTV and related viruses with multipartite genomes package their genomes into capsids has proved elusive until very recently. The ten BTV RNA segments (3.95–0.8 kb) vary in sequence but share common complementary short 5' and 3' untranslated regions (UTRs) of variable length, which include highly conserved hexanucleotides at both ends. Recent evidence has shown that the sorting of BTV RNA segments starts by the recruitment of genomic ssRNAs via these UTRs. Further, intersegment interactions leading to complex RNA networks are the driving force for sorting and packaging of a correct set of genomic segments. There is a specific order of segment recruitment, the smallest segment, S10, triggers RNA-RNA interaction with other three small segments and forms the initial complex. The other six larger ssRNA segments are subsequently recruited in a size dependent manner to form the final complex. Highly specific segment assorted signals (SAS) dispersed across the ssRNA segments are responsible for driving the specific interactions between RNA segments and thereby promoting RNA complex formation. Perturbation of these SAS by mutagenesis or by the introduction of specific competitive oligoribonucleotides, disrupts the RNA assembly process and affects RNA packaging in vivo. These studies indicate how selective packaging is achieved for BTV and suggest that similar mechanisms may apply to other members of the *Reoviridae* family.

Virion Maturation and Egress

Upon core assembly and dsRNA synthesis, nascent cores dissociate from the VIBs and the outer capsid proteins VP2 and VP5 are rapidly recruited to the core generating the mature virus particles. The precise mechanism behind the recruitment of VP2 and VP5 is not yet known, but it is likely that host factors are involved, VP5 with lipid raft and VP2 with vimentin and, in addition, both proteins have been found to concentrate on the surface of intracellular vesicles in preparation for their recruitment.

The release of the mature virus particles can be either lytic or non-lytic, with the host cell influencing the mechanism of egress. Infection of mammalian cells results in extensive cytopathic effect, such that the egress in these cells is predominantly by cell lysis although non-lytic budding has been also documented. In contrast, infected insect cells show little or no cytopathic effect and infected cells are characterized by continual non-lytic budding of nascent virus.

Non-lytic egress is primarily mediated by the viral glycoprotein NS3/3A, which is predominately found anchored to the plasma membranes and associated with the intracellular vesicles together with VP2 and VP5. It has been predicted that this protein forms homo-oligomers in infected cells and possesses a viroporin activity. The NS3/3A has two transmembrane domains with a short extracellular domain between them and the N and C termini project into the cytoplasm. The short C-terminal domain interacts with nascent viral particles via the outermost structural protein VP2, while the N-terminal domain of NS3/3A is capable of recruiting several host components of trafficking and exocytic pathways as well as the endosomal sorting complex required for transport (ESCRT) pathway. At the plasma membrane, NS3 directly binds to the membrane and facilitates the budding process. It has been shown that the NS3 protein is present in the envelope surrounding budding particles, and in cholesterol enriched membrane patches in close association with VP5 protein that also possessed an autonomous membrane-targeting signal. Finally, NS3 recruits TSG101, another ESCRT component, which eventually promotes scission of the budding viruses. Together these cellular factors are thought to traffic NS3/3A, along with the bound virus, to the plasma membrane. Thus, NS3/3A can be considered a bridge linking the virus particle to essential cellular trafficking machinery.

The importance of NS3/3A to non-lytic egress was highlighted in studies using an NS3/3A defective virus. These viruses remained viable in mammalian cells, although with less efficiency, however, they were dramatically attenuated in insect cells. Altogether, these findings describe a striking role for the NS3 protein in mediating viral egress, using mechanisms similar to those described for enveloped viruses.

Epidemiology

Bluetongue virus alternates its infectious cycle between the insect *Culicoides* vector and ruminant mammals. In many countries, the prevalence of BTV infection is high in ruminants although clinical disease is often not recorded. Due to the presence of *Culicoides* midges, the disease is prevalent throughout the tropics and subtropics, within separate ecosystems. The chance of infection depends in part on the genotype of the midge, the strain of virus, the level of viremia, and environmental factors. The epidemiology of bluetongue disease can be considered in the context of three major zones of infection: an endemic zone (generally subclinical infection), an epidemic zone (disease occurs at regular intervals), and an incursive zone (disease occurs usually only at extended intervals, but when it does occur, the epidemic is often extensive). Seasonal incursions of the virus into more temperate latitudes, sometimes accompanied by

disease, may occur under favorable climatic conditions at certain locations. Interestingly, cases of major epidemics in regions where disease occurs only sporadically, have often been traced to windborne transport of infected *Culicoides* from distant areas.

Many BTV strains have been isolated from different sources since its first characterization in the early 1900s. Initial cross-immunity studies of multiple BTV strains and subsequent serum-virus neutralization tests confirmed the existence of multiple serotypes of BTV. The complete virion particle was purified in 1969, and subsequent gel electrophoresis analysis showed that the BTV genome contained 10 discrete dsRNA segments. The genetic diversity and variation in sequences of different genome segments within a single BTV serotype was identified initially by RNA oligonucleotide fingerprint analyses of BTV field samples, which demonstrated that both genetic drift and genetic shift contribute to BTV evolution. Nevertheless, some segments were clearly less variable within a single serotype, but more variable between types, than others (e.g., segments encoding outer capsid proteins). Further, field isolates from both animals and insect vectors consisted of mixtures of RNA segments from populations of circulating virus strains. High-frequency of genome segment reassortment was shown to occur readily between different BTV serotypes and within other orbivirus serogroups but not between viruses belonging to different serogroups.

Early molecular hybridization studies demonstrated that genome segments 2 and 5 (encoding the two outer capsid proteins) exhibited little or no cross-hybridization between serotypes, whereas the other eight RNA segments gave consistently higher hybridization signals. Thus, genome segment reassortment may be an important factor in the generation of genetic diversity in orbivirus populations in nature.

These results were initially confirmed by sequence comparisons of segments encoding VP5 and VP2 from six different serotypes in the 1980s. This was further affirmed by recent extensive phylogenetic analyses of more than 200 different isolates of different serotypes. The accumulating data suggested that while VP5 showed up to 70% sequence identity, VP2 sequences varied from 22% to 73% between serotypes. While BTV isolates can be separated into twenty eight distinct serotypes on the basis of genome segment 2, localized circulation of the virus in different regions throughout the world has led to evolution of distinct geographical variants broadly divided into Eastern (endemic in Asia, Indonesia and Australia) and Western lineages (endemic in Africa, the Caribbean and the Americas). Serotypes have additionally been classified into distinct nucleotypes based on phylogenetic analysis of segment-2 (VP2) and segment 5 (VP5). VP2 was classified into 12 nucleotypes: A-L that correlates with BTV serotypes while VP5 was classified into 10 nucleotypes: A-J and have partial correlation with BTV serotypes.

The global distribution of different BTV serotypes has undergone drastic alteration over the recent years. Changes in climate and increased travel and trade have been implicated in the global distribution of BTV, and of *Culicoides* species susceptible to BTV infection. Molecular epidemiology studies indicate that individual strains can move large distances due to the windborne movements of infected insects and that a single bite from a fully infected adult *Culicoides* is sufficient to reliably transmit the virus to a susceptible mammalian host.

Many serotypes of BTV previously not present, have now been detected in Europe, North America, Australia, Korea, India, the Middle East, and South America, with more than one BTV serotype identified in many regions. Particularly in Europe, the epidemiology of BTV has changed dramatically since 1998, when six different BTV serotypes emerged across southern European countries. Most of these serotypes have persisted and spread both westwards and northwards, providing evidence for an epidemiological 'step-change'.

By 2002, different BTV serotypes were identified in Greece, Italy, Bulgaria, Kosovo, Serbia, Montenegro, Macedonia, Croatia, Albania, and Bosnia and Herzegovina. Several serotypes gradually spread north and in particular, a BTV-8 epidemic broke out in northern Europe in 2006 with the first case being reported in the Netherlands. Outbreaks of BTV-8 were then reported in Belgium, Germany, and Northern France although the exact mode and mechanism of these incursions remains unclear. BTV-8 subsequently spread across southern European countries and further north into Luxembourg, the Czech Republic, Switzerland, Denmark, and the UK. New outbreaks were also reported in Hungary, Austria, Sweden, and Norway. In 2008, BTV-6 was identified in Germany and the Netherlands and BTV-11 was identified in Belgium. The high number of cases reported for the BTV-8 outbreak in Belgium, Germany, Netherlands, France, and Luxembourg, led to the implementation of a vaccination strategy against the serotype across several countries in Europe, and the outbreak was finally controlled in 2009.

Pathogenesis and Clinical Features

BTV is transmitted to vertebrate hosts through blood-feeding midges of the *Culicoides* genus. BTV infection has an incubation period of 4–12 days and produces a spectrum of conditions from sub-clinical infection to severe and fatal disease, depending on virus strain and host species. Clinical signs of infection are generally more severe in sheep, resulting in severe illness and high mortality (as high as 70%). The insect vectors carry the virus in their salivary glands and ducts and infect the host during a blood meal with virus inoculation at the site of biting. The regional lymphatic system underlying the infected skin laceration mediates the dissemination of the virus to the endothelial cells, and peripheral blood mononuclear phagocytes (PBMs). The virus proliferates in the PBMs and lymph nodes and is further disseminated via the blood stream to sites of secondary infection. In the final phase of infection, the virus begins circulating in the bloodstream. Viral RNA can persist for several months. BTV binds to glycoporphins on the surface of bovine and ovine erythrocytes where it may remain in an infectious state as invaginations of the erythrocyte cell membrane. This minimizes contact with antibody and T cells and thus provides multiple opportunities for transmission by infection of blood-sucking midges.

In sheep, viremia is usually detectable around 3–5 days post infection. During the initial stages the virus associates with both platelets and erythrocytes, however, in the late stages of infection, the virus is associated exclusively with erythrocytes, facilitating

the prolonged infection of ruminants and increasing transmission to the insect vectors that feed on them. BTV infection of mammalian cell lines induces cell death, either by triggering multiple apoptotic pathways or via necrosis. BTV replication in endothelial cells causes cell injury and infected ruminants develop lesions due to mononuclear cell infiltration. The accumulation of large acidophilic intra-cytoplasmic masses which, results in degeneration and necrosis. Infected ruminants suffer severe systemic damage, characterized by widespread edema and hemorrhage. In infected sheep with severe disease, swelling of the tongue and lack of oxygen make the tongue and mucous membranes appear blue (hence the name of the disease). Infection of pregnant cattle and sheep with BTV can result in maternal death, abortion, and fetal death, or congenital anomalies. BTV infection in most wild ruminant species is typically asymptomatic or subclinical, although in some cases severe disease in cattle and camelids has been described. Infected cattle and goats sporadically display clinical signs including nasal discharge, swelling, and, ulceration of the mouth.

Diagnosis

Since bluetongue is a notifiable disease, animals diagnosed with clinical signs of bluetongue disease and pathology are required to be reported to local health officials. BTV infection is confirmed by virus isolation, detection, and characterization of the infecting serotype. Earlier methods relied primarily on serological tests to detect BTV antibodies in infected animals. Complement fixation, agar gel immunodiffusion (AGID) and haemagglutination-inhibition relied on virus/serum neutralization methods that enabled virus serotype identification based on the interaction of the outer capsid protein VP2 with serotype-specific antibodies. Among the various serogroup-specific assays for antibody detection, AGID and competitive enzyme-linked immunosorbent assay (cELISA) are the most widely used. However, although the AGID test is simple to perform and rapid, it is not highly sensitive or quantitative and has limitations in its specificity. In contrast, the cELISA, in which a group-specific monoclonal antibody based on BTV core protein VP7 is used, has proved to be the most sensitive and specific assay for detection of antibodies to most, if not all, serotypes and strains of BTV. Following extensive national and international validation, the cELISA became a universal test to certify ruminants for trade purposes and to diagnose BT infection in domestic and wild animals. The test is highly specific and sensitive detecting antibodies to most, if not all, serotypes and strains of BTV. For the detection of serotype-specific antibodies in animal sera, the cell culture-based microtiter serum neutralization (MTSN) is the most commonly used assay. MTSN is often used to monitor animal population for specific serotypes of BTV in epidemiological investigations.

Recent advances in molecular and high-throughput sequencing technologies have enabled rapid identification of newly isolated strains by reverse transcription PCR (RT-PCR) assay, real-time RT-PCR, or sequencing specific segments that are highly variable across the different isolates. RT-PCR assays employing serotype-specific primers have provided the most rapid and specific information regarding isolate serotype. Selective sequencing of virus segments or whole genome sequencing provides serotype as well as other unique sequence information of isolates. These new approaches have enabled rapid and reliable confirmation of BTV serotype, and are potential methods that should be applied at the onset of an outbreak to allow for the early selection of vaccine.

Vaccination and Control

Vaccination strategies in different countries have been developed according to their individual policies, the geographic distribution of the circulating BTV serotypes and the availability of appropriate vaccines. In South Africa, the country where bluetongue was first characterized, live attenuated virus vaccines have been used for over 50 years and are known to induce an effective and lasting immunity. Due to the high number of circulating serotypes however, live modified vaccines often have to be administered as a multivalent vaccine. Despite their success in endemic areas, these attenuated virus vaccines have exhibited some drawbacks, including abortion/embryonic death and teratogenesis in fetuses of pregnant females. In addition, the strength of the protective antibody response to attenuated vaccines correlates directly with their ability to replicate in vaccinated animals and when responses are sub-optimal viremia is observed that is sufficient for the vaccine strain to be transmitted to biting midges. Furthermore, there is a likelihood of reversion to virulence and/or reassortment of the vaccine strain with wild type viruses.

In recent years, chemically inactivated BTV vaccines were used for mass vaccination of sheep and cattle in European countries during the BTV-8 and BTV-1 outbreaks. While these inactivated virus vaccines have been demonstrated to be safe and immunogenic in animals, they are only available for a limited number of serotypes. Additionally, in some cases adverse reactions have been associated with some of these inactivated virus preparations. Inactivated vaccines generally induce relatively transient immunity in comparison to live, attenuated vaccines and require booster immunizations. The high cost of vaccine production due to the need for large amounts of antigen required for each vaccination is another major drawback.

The biggest limitation to the use of both the live attenuated and inactivated vaccines is the significant economic impact they have on agricultural trade. These vaccines do not allow the differentiation of naturally infected versus vaccinated animals (DIVA) as these vaccine strains are not free of viral protein components that interfere with serological tests. Thus, neither of these vaccines is DIVA compliant and restrictions are imposed on animal trade and movement if an animal is diagnosed positive, even if that positivity is the result of vaccination. Further, due to the presence of genomic RNA after vaccination and short-term BTV viremia in animals in the case of the live attenuated vaccine, a genetic DIVA is not always feasible.

A number of recombinant protein technologies have been employed in order to provide DIVA compliant vaccine candidates and to reduce the potential adverse effects associated with inactivated and attenuated virus vaccines. Recombinant proteins have

predominantly been assessed in sheep in experimental vaccination challenge trials and shown to afford protection, but have yet to be commercialized. Recombinant outer capsid protein VP2, the serotype determining protein, could indeed elicit protective neutralizing antibody in vaccinated animals and later studies, which combined both outer capsid proteins (VP2 + VP5) resulted in better protection than VP2 alone in vaccinated sheep. In addition, VP2-based vaccines have been developed using other live virus vector systems (i.e., poxviruses, herpesvirus, and adenovirus), which have been designed to express either a single or multiple proteins in animals following vaccination.

Enhanced protective immunity afforded by recombinant VP2 + VP5 led to the development of recombinant virus-like particles (VLPs) containing the VP2 + VP5 and the two core proteins (VP3 and VP7), mimicking the virus particles without the viral genome or enzymatic proteins. The VLPs had the characteristic icosahedral structure with the four recombinant proteins in the same position and ratios as the native proteins. Multiple vaccination studies with homologous and heterologous VLPs (~10 µg) resulted in complete protection against virulent virus challenges in sheep. In recent years, extensive vaccination trials with VLPs of European serotypes had been undertaken in European breeds of sheep. These trials have also assessed VLPs delivered singly or in cocktail, as well as the evolutionary lineage of the virus strains, in order to assess their potential for commercialization.

The influence of evolutionary divergence (Eastern and Western topotypes) on vaccine development has clearly highlighted that the development of serotype specific neutralizing antibodies was more critical than the topotype of the circulating strain. This suggested that isolate variation or evolutionary distance of the strain is not critical for BTV vaccines. Furthermore, the delivery of VLPs as a cocktail of different serotypes did not limit the ability of each serotype to raise a serotype specific neutralizing antibody response or to interfere with the protective efficacy of the vaccine when animals were challenged. These findings have indicated that multiple serotype vaccines could be developed using known serotypes rather than generating new vaccines for each BTV outbreak. Most importantly, it is possible to distinguish between VLP-vaccinated animals and those that are infected with the virus, thus addressing one of the major problems with current vaccines. Further, VLPs are entirely protein-based and there is no genetic component avoiding all issues of reversion or recombination.

The use of the BTV reverse genetics system has further allowed direct introduction of mutations/deletions in the viral genome leading to the recovery of replication-defective virus strains using specific complementary cell lines. Entry Competent Replication Abortive (ECRA) vaccines, formerly known as Disabled Infectious Single-Cycle (DISC) vaccines were designed based on this principle. The ECRA vaccines are modified particles that contain only 9 of the 10 genome segments, they lack the essential catalytic gene VP6, and are hence replication incompetent. The defective virus can enter susceptible cells where they undergo a single cycle of replication but fail to make progeny virus due to the inability to package the dsRNA genome. Administration of ECRA vaccine results in expression of the viral proteins at the site of infection but does not cause infection in animals and hence combines the efficacy of live-attenuated vaccines with the safety of inactivated vaccines. Recent trials in cattle and sheep have shown promising results. A single dose of a DISC virus strain was sufficient to confer complete protection against a challenge in sheep 42 days after vaccination while a cocktail of six different vaccines protected animals as early as 21 days against any challenge with virulent strains. The animals were completely protected from challenge with individual virulent serotypes, even after 5 months of challenge without any clinical disease. ECRA vaccines are more cost-effective and since they are replication incompetent, the ECRA RNA segments are present in the bloodstream for a very short period thus minimizing the risk of transmission via insect vector, reassortment, or reversion to virulence.

A second RG based candidate vaccine strain has been made against BTV known as Disabled Infectious Single-Animal (DISA), in which segment 10 is deleted, encoding NS3/NS3A. Unlike the ECRA strains, the DISA strain still replicates in normal cells and in sheep although it is significantly attenuated. The DISA vaccine strain is also DIVA compliant and is another promising candidate vaccine although rigorous animal studies are still lacking.

While a completely new range of different vaccine candidates, showing promising levels of efficacy and safety, have been developed recently, none of them are near commercial production. The voluntary vaccination policy adopted in Europe and the acceptance of endemic disease in many parts of the world has resulted in a dearth of commercial organizations interested in producing these new vaccines. Given the likelihood of new BTV outbreaks across Europe, there is however, a need to develop suitable vaccines that can be produced efficiently as vaccination is the best way to control outbreaks.

Future Perspectives

The advances in understanding BTV, at all levels, has led to it being one of the most well characterized RNA viruses, including the details related to its replication in both mammalian and insect hosts. Physically the resolution of the virion structure has increased substantially and the atomic detail of nearly all of the particle is now known. This level of understanding has provided insights on how the particle disrobes on entry and crosses the membrane to enter the cytoplasm. We also have a greater understanding of how transcription and replication proceed. Importantly, key insight has been obtained on how multiple segmented dsRNA genomes are incorporated into assembling virions, while cellular messenger RNAs are excluded. The role of cellular factors and virus encoded proteins in leading the virus out of the cell has never been better described.

Yet despite this phenomenal progress, much remains to be learned. The structure of the particle, while instructive, does not represent the dynamic aspects of the capsid, that is less understood. The level of “breathing and the triggers” for channel opening to allow the initiation of transcription of the assembled particles are still unclear. How VP5 leads to membrane destabilization is also not well understood. BTV is a large particle and it is difficult to envisage it crossing a membrane barrier with ease.

The dynamic nature of VIB is another area of uncertainty and while its description as a virus factory is true, it does not address how exactly all BTV components coalesce there or how, after assembly, the newly formed virions leave this amorphous mass in an orderly fashion. What are the triggers and timings of these processes and do they pertain to all cell types or only to some? Virions acquire their outer layer as it migrates the cell to the exterior. A role for an “enveloped” BTV has been proposed, but detail is sketchy. Not least, the astonishing difference in CPE observed in mammalian and insect cells is something that requires a much more work.

Behind all experimental approaches, molecular, structural or immunological, is the desire to see new findings translated into improved options for disease control. Here, recent progress has been promising with some clever approaches to the generation of candidate vaccines that include DIVA compliance. Better yielding and genetically tighter variants will certainly be produced in the future opening the possibility that such intricately engineered vaccines may become the default for future outbreak control. Bluetongue is a disease with economic repercussions in both developed and developing countries. Hence, better control measures have the opportunity to improve also the quality of life for the livestock of subsistence farmers, which in turn can have knock-on benefits, to the communities that depend upon animal productivity.

Borna Disease Virus and Related Bornaviruses (*Bornaviridae*)

Susan L Payne, Texas A&M University, College Station, TX, United States

© 2021 Elsevier Ltd. All rights reserved.

Introduction

The name bornavirus derives from Borna disease, a rare neurologic disease that mainly effects horses and sheep. The disease presents as an array of behavioral changes including ataxia, head tilt, muscle fasciculation, hind limb paresis, localized hypo- or hyperesthesia, disturbances in chewing and swallowing, and aggression. Borna disease is endemic in a fairly small geographic area encompassing central and southern Germany and neighboring countries. The disease name is linked to two major outbreaks that occurred from 1894 to 1896, among cavalry horses near the town of Borna, Germany. The infectious nature of Borna disease was not confirmed until the early decades of the 20th century and it would take approximately another 50 years before persistently infected cell cultures were established. However, even then the infectious agent remained uncharacterized because persistently infected cultures did not provide sufficient cell-free virus for convincing biochemical or structural studies. Finally, in the early 1990s molecular studies revealed the similarities of Borna disease virus (BoDV-1) to other unsegmented, negative strand RNA viruses.

Classification

Until 2008 BoDV-1 was the sole member of the family *Bornaviridae*. In 2008 novel bornaviruses were identified as the etiologic agents of proventricular dilatation disease (PDD) of birds. Identification of these avian bornaviruses was accomplished by using nucleic acid hybridization and unbiased high throughput sequencing techniques. Since 2008, polymerase chain reaction (PCR) and unbiased nucleic acid sequencing methods have been used to identify additional bornaviruses. Currently the International Committee on the Taxonomy of Viruses Master Species List contains 10 species of bornavirus. Two species have been isolated from mammals (Mammalian 1 orthobornavirus and Mammalian 2 orthobornavirus), 5 from birds (Passeriform 1 orthobornavirus, Passeriform 2 orthobornavirus, Psittaciform 1 orthobornavirus, Psittaciform 2 orthobornavirus and Waterbird 1 orthobornavirus) and 3 from snakes (Elapid 1 orthobornavirus, Queensland carbovirus, and Southwest carbovirus).

Virus Structure

Bornavirus virions are enveloped and are assumed to have a helical nucleocapsid; their size is broadly estimated to be 80–130 nm in diameter. However, unlike many viruses, detailed ultrastructural analyses of bornavirus virions have not been performed, due to the highly cell-associated nature of the virus. The illustration of a bornavirus particle shown in [Fig. 1](#) is theoretical, based on relatively low resolution electron micrographs of virions and the known structures of other unsegmented negative strand RNA viruses.

Genome

The genome of bornaviruses is a single negative stranded molecule of approximately 8.9 kb in length. The genome organization of mammalian and avian bornaviruses is highly conserved ([Fig. 2](#)) and similar to other members of the order *Mononegavirales* ([Fig. 2](#)). Bornaviruses contain 6 open reading frames and short non-coding regions are found at the 5' and 3' ends of the genome. Bornavirus genomes lack the discrete intergenic sequences characteristic of the paramyxoviruses and rhabdoviruses. Instead, transcription termination sequences for upstream transcripts are found just downstream of initiation sequences for the next transcript.

A promoter near the 3' end of the BoDV-1 genome initiates the N transcript, the most abundant viral transcript. The N transcript is used to produce two isoforms of N, p40 and p38 by use of alternative start codons. The X/P transcript produces two proteins, X and the phosphoprotein P. X and P are produced from overlapping reading frames. P is a 24 kDa phosphoprotein that serves as a co-factor for L, the catalytic subunit of the transcription/replication complex. The 10 kDa X protein interacts with P and has role in RNA replication. X also associates with mitochondria and prevents induction of apoptosis in infected cells. A third transcription start site is used to produce the M, G and L transcripts; both G and L are spliced. M (p16) is found in both the cytoplasm and nucleus of infected cells. M co-localizes with N, P, and X in punctate structures in the nucleus. As shown in [Fig. 2](#), there are short overlaps of the M, G and L reading frames. The glycoprotein, G, is post-translationally modified by N-glycosylation to yield a 93-94-kDa primary product. G contains a proteolytic cleavage site and a portion of G is cleaved to produce amino terminal (G-N) and carboxyl terminal (G-C) products. Virus neutralization studies have demonstrated the importance of G in virus entry.

Life Cycle

Most molecular studies of bornaviruses replication have been carried out using BoDV-1, but it is likely that mechanisms of transcription and genome replication elucidated for BoDV-1 will hold true for the avian bornaviruses as well. Bornaviruses are highly cell-associated, however some infectious particles are released from infected cells. In the case of cell-free virus, bornavirus G is the candidate for receptor attachment and subsequent fusion, but host receptors have not been determined. Although the molecular details are not yet known, it is clear that the nucleocapsids traffic to the nucleus where transcription initiates. L catalyzes RNA synthesis and likely serves to cap and polyadenylate viral mRNAs. Translation of N, X, P, M and L are cytosolic, while G is processed in the endoplasmic reticulum. All viral proteins with the exception of G are transported back into the nucleus where genome replication and assembly of ribonucleoprotein particles (RNP) occur. Immunostaining of persistently infected cells shows large punctate structures in the nucleus. These so-called vSPOTS are virus replication factories with a size of ~66 µm in diameter. vSPOTS are cage-like assemblies of the N protein with 59–180 nm pores. Viral genomes and the proteins X, P, M and L are also found in vSPOTS, therefore these structures contain all of the components necessary to be sites of transcription and/or genome replication.

Filamentous viral RNPs, containing genomic RNA, N, P, X and L, associate with chromatin by using core histones as a docking platform. High mobility group box protein 1 (HMGB1), a chromatin-remodeling DNA architectural protein binds to viral P, stabilizes the RNP on chromosomes and appears to be required for efficient transcription. In mitotically active cells, the tight association of the RNP with chromatin facilitates transmission of RNPs to daughter cells. Within infected hosts, virus (in the form of RNPs) spreads long distances along neural networks to access the CNS. RNPs appear to move along axons in signaling endosomes. There is little to no free virus in the infected animal. In a cockatiel model of avian bornavirus infection, virus injected into pectoral muscle reached the spinal cord at about 20–25 days post-inoculation. From there virus spread quickly to the brain. From the CNS, virus spread to ganglia in the gastrointestinal tract, adrenal gland, heart, and kidneys. At late points of infection (80–100 days) viral antigen was also seen in smooth muscle and/or scattered epithelial cells of numerous tissues.

Epidemiology and Clinical Features

Borna Disease

The white-toothed shrew (*Crocidura leucodon*) is the animal reservoir for BoDV-1 in Borna disease endemic areas. The virus replicates in numerous tissues in the shrew and is excreted into the environment. In shrews the virus causes persistent infection without signs of disease. Borna disease, caused by infection with BoDV-1, is quite rare and predominantly affects horses and sheep in Central Germany. There is no evidence that the virus is naturally transmitted among infected livestock, therefore horses and sheep are 'accidental' and dead-end hosts.

Disease is often fatal. Signs include ataxia, head tilt, muscle fasciculation, hind limb paresis, localized hypo- or hyperesthesia, disturbances in chewing and swallowing, and aggression. Grazing animals, in particular horses and sheep, likely inhale excreted virus and are infected by the olfactory route. The incubation period last from weeks to months as virus moves from the initial site of infection to the central nervous system.

Staggering Disease in Cats

Beginning in the late-1970s, a neurologic disease characterized by stiffness, leading to paralysis and death was observed in cats in Central Europe and Scandinavia. Histopathology of affected cats revealed lymphohistiocytic inflammation of the CNS. In the 1990s BoDV-1 nucleic acids were isolated from some of cats with staggering disease, and challenge of pathogen-free cats with this virus induced neurologic disease. Staggering disease has been reported in cats world-wide and serologic surveys of healthy cats reveal that many are also positive for bornaviral antigens. Studies in Japan show approximately 25% of tested cats are positive for bornaviral antigens by Western blot assays. This is similar to findings in birds (see below) and underscores the fact that many BoDV-1 infections are asymptomatic. Epidemiology of bornavirus infection in cats in Japan points to vertical transmission, while reports from Europe suggest cats with outdoor access are at higher risk for developing staggering disease. For these cats, infection likely results from predation upon birds, rodents and/or other small mammals. In one European study, approximately 80% of cats with staggering disease tested positive for bornavirus-specific antibodies by immunofluorescence assays, compared to 16% of a healthy comparison group.

Bornavirus Associated Encephalitis in Humans

Beginning in the 1980s there were efforts to link human bornavirus infection and psychiatric disorders. Many of the early studies claiming positive links relied on poorly described serologic techniques and many other studies failed to show links. However, while the relationship between bornavirus infection and human psychiatric disease remains unclear, three recent case reports provide striking evidence that mammalian bornaviruses can cause severe, fatal neurologic disease in humans. In all, 6 human deaths have been strongly associated with bornaviral infection. The first case report of fatal human bornavirus infection involved

Fig. 3 Fluorescent antibody labeling of duck embryo fibroblasts infected with an avian bornavirus. A focus of infected cells (green) sits amidst uninfected cells. The uninfected cells are visualized by DAPI staining (blue) of their nuclei. From: Payne, S., 2017. Chapter 22 – Family Bornaviridae. In *Viruses* (edited by S. Payne), Academic Press, pp. 191-196, <https://doi.org/10.1016/B978-0-12-803109-4.00022-2>.

three breeders of squirrels in Germany that presented with encephalitis between 2011 and 2013. All three died within 2–4 months after onset of symptoms. After eliminating suspected causes of encephalitis, a genomic approach was used as a means of identifying novel pathogens. This approach revealed common bornaviral sequences in the brains of the three victims. Exchange of breeding squirrels linked the three human victims and an identical viral sequence was recovered from the brain of a variegated squirrel (*Sciurus variegatoides*). The squirrel bornavirus, (named variegated squirrel 1 bornavirus (VSBV-1) is phylogenetically distinct from BoDV-1 and is a member of the species Mammalian 2 orthobornavirus).

Another case report from 2018 underscores the danger of handling squirrels. This report describes a fatal case of limbic encephalitis in a zoo caretaker in Germany. Molecular assays and immunohistochemistry revealed a limbic distribution of viral antigen in brain tissue. Sequencing and phylogenetic analysis of the brain-associated virus demonstrated a likely spillover infection from a Prevost's squirrel (*Callosciurus prevostii*). Prompted by the human cases of VSBV-1, studies of squirrels have been carried out in order to assess the risk of infection. Small numbers of VSBV-1 infected squirrels have been detected among small breeders and zoos in Germany, the Netherlands and Croatia. The variegated squirrel is a native of southern Mexico and Central America while the Prevost's squirrel is a native of Asia, thus the origins and natural reservoirs of VSBV-1 are unknown.

Organ transplantation is another source of human bornavirus infection. A 2018 report presents strong evidence of BoDV-1 infection transmitted via solid organ transplant. As described in the case report, the organ donor was a 70 year old man from the Bavarian region of Germany who had no signs or symptoms of neurologic disease. Two recipients of kidneys developed neurologic disease that progressed to irreversible coma. A third patient, who received a liver graft, developed transient neurologic deficits but went into remission from the disease. A metagenomics analysis of brain tissues from the two deceased organ recipients was performed, revealing BoDV-1 sequences. Immunohistochemical analysis also revealed bornaviral antigens in brain tissues. Antibodies to BoDV-1 were detected in the third organ recipient. It is interesting to note that to date, these well-documented cases of bornavirus-associated encephalitis in humans have occurred in Central Europe, in Borna disease endemic areas. It remains to be seen if additional cases of fatal human encephalitis will be linked to bornavirus infection in the future.

Proventricular Dilatation Disease of Birds

PDD is a fatal neurologic condition first recognized in the mid-1970s among captive parrots. A viral etiology was suspected early on, but the agent was not identified until 2008 when the genomes of novel bornaviruses were identified in the brains of affected birds. Infectious viruses were quickly recovered and used to produce PDD in experimental infections. While large parrots and macaws are the captive birds most likely to be diagnosed with PDD, the disease has also been described for other pet birds such as canary birds and finches. Clinical neurologic signs of PDD include weakness, ataxia, proprioceptive deficits, seizures, and blindness. Gastrointestinal malfunctions are also very common and result in severe weight loss, passage of undigested food, regurgitation and delayed crop emptying. Gastrointestinal malfunction results in the most common gross pathologic lesions associated with PDD – dilation and thinning of the walls of the proventriculus and ventriculus. Histopathologically, PDD is characterized by nonsuppurative inflammation in the central, peripheral, and autonomic nervous systems.

ABV infects primarily the central and enteric nervous systems of birds. In experimental models, virus is inoculated into muscle tissue and onset of disease is highly variable, but is typically from several weeks to months. Although the virus is noncytopathic examination of brain tissue reveals selective loss of glial cells and neurons. Based on the known pathogenesis of Borna disease, it is believed that cell loss is due to T cell cytotoxicity rather than direct cytopathic effects of the virus. Treatment of affected birds with immunosuppressive agents can suppress or delay disease development in experimental models, supporting an immunopathologic basis for the disease.

Fig. 4 Microscopic lesions from a birds with avian bornavirus infection and PDD showing lymphocytic infiltration (dark purple cells) (left) and presence of bornavirus antigen (discrete areas of dark brown staining) in neurons (right). From: Payne, S., 2017. Chapter 22 – Family Bornaviridae. In Viruses (edited by S. Payne), Academic Press, pp. 191-196, <https://doi.org/10.1016/B978-0-12-803109-4.00022-2>.

In birds, bornavirus replication is not restricted to neurons. Lymphocytic infiltrates and viral antigens and nucleic acids are abundant in the heart, kidneys, adrenals, gonads and skin (Fig. 4). Bird droppings contain viral nucleic acids and droppings have been used a source of infectious virus. Droppings are a likely vehicle for transmission of avian bornaviruses but it is interesting to note that attempts to experimentally infect birds via the oral or intranasal route have, to date, been unsuccessful.

The first clues to bornavirus infection of waterfowl came from retrospective surveys of Canada geese and trumpeter swans suffering from neurologic disease of unknown origin but with neuropathology consistent with PDD. These studies were carried out at the Ontario Veterinary College, Guelph, Ontario, Canada. Bornaviral sequences and antigens were present in brain tissues of many affected birds. Subsequent surveys of healthy birds (hunter harvested, or culled as nuisance birds at airports and landfills) revealed that avian bornaviruses infection is widespread in North America and Europe. In North America, bornaviruses have been detected in the brains or urofeces of Canada geese (*Branta Canadensis*), snow geese (*Chen caerulescens*), Ross's geese (*Chen rossii*), trumpeter swans (*Cygnus buccinator*), mute swans (*Cygnus olor*) and a variety of ducks and gulls. The majority of waterfowl infections are associated with the species Waterbird 1 orthbornavirus. The virus has also been detected in raptors suggesting that predation may be a source of infection. The overall impact of bornavirus infection of wild bird populations remains unknown.

Endogenous Bornavirus-Like Elements

In recent years, whole genome sequencing has revealed insertions of many non-retroviral genome fragments into the genomes of diverse animal species. Among the viral genome fragments discovered in animal genomes are those of bornaviruses. Fragments of bornavirus genomes have been detected in fish, snakes, turtles, bats, rodents, squirrels, elephants, nonhuman-primates, and humans. Phylogenetic analyzes show that the establishment of endogenous Borna-like (EBL) elements took place took place as multiple independent events, as long as 65 million years ago. Bornavirus N, M, G and L genes are present in eukaryotic genomes. EBLs are derived from viral mRNAs and evidence supports a role for LINE-1 retrotransposition.

Some EBLs comprise complete open reading frames and indeed, some are expressed. In humans there are seven EBL N elements (EBLNs) and all are expressed in at least one tissue. Robust protein expression of Homo sapiens EBLN-1 (hEBLN-1) occurs in various cancer-derived cell lines and it functions in regulation of genome stability and cell cycle. Knockdown of hEBLN-1 RNA results in abnormal cell growth, arrest of cell cycle at G2/M and increased apoptosis. In an experimental system, the thirteen-lined ground squirrel (*Ictidomys tridecemlineatus*) EBLN inhibits the replication of BoDV-1 in cell cultures by suppression of polymerase activity. Thus, some EBLs may play roles in intrinsic immunity to bornaviruses.

Pathogenesis

Non-cytopathic infection and persistence are hallmarks of bornavirus infection, both in cultured cells and within the infected host. Relatively few infectious virions are produced as bornaviruses are highly cell-associated. Immunostaining of infected cell cultures reveals slow 'spread' of the virus as infected cells divide (Fig. 3). Infected cells undergoing mitosis reveal chromatin associated 'particles', suggestive of RNPs, being distributed to daughter cells.

In the infected host, suppression of innate immune responses may favor establishment of infection and viral persistence. Bornaviruses have redundant mechanisms by which they interfere with innate responses.

BDV N interferes with the IKK/NF-κB pathway by inhibiting the cleavage of NF-κB1 p105. N also interferes with IRF7 activation (prevents nuclear localization) and interferon (IFN) type 1 expression. P inhibits the activation of type I interferon (IFN) as well,

through the TBK1-IRF3 pathway. BDV X interferes with IFN signaling and also localizes to mitochondria, blocking apoptosis mediated by the mitochondrial signaling protein MAVS.

Other factors that favor persistence in the infected host include regulation of transcription and genome replication. An interesting and unique feature of bornavirus genome replication is truncation of genome strands. Many genomes cloned from persistently infected cells are truncated and lack sequences required for genome replication. It is speculated that this process leads to down-regulation of replication and or transcription. Genome truncation would also remove 5' terminal triphosphates from RNA, leaving 5' monophosphate ends, providing a mechanism for avoiding recognition by RIG-I.

In horses and sheep, BoDV-1 is exclusively associated with neurons. Virus replication is non-cytopathic but in response to infection, large numbers of T-lymphocytes infiltrate the CNS and are found at sites of virus replication. Thus, there is an immune mediated component to BoDV-1 pathogenesis.

Laboratory rodents are used as models for BoDV-1 infection (although rodents vary greatly in their susceptibility to BoDV-1 infection and different model systems employ specific rodent and virus strains). In the rodent model, virus replication is restricted to neurons and virus spreads through neural networks, similar to the case of rabies virus. BoDV-1 mainly targets hippocampal neurons, but also infects astroglial and oligodendroglial cells in the brain. The outcome of infection depends on the genetic background, age of infection and immune status of the animal. Infection of adult, immunocompetent rats results in an encephalitis similar to that seen in natural infections. It has been clearly demonstrated that encephalitis is immune-mediated, with cytotoxic T-cells being the major players. The pathology of the immunocompetent rat model is identical to the natural infection of horses and sheep. In contrast, experimental infection of neonatal rats (not yet immunocompetent) or immune-suppressed rats, leads to persistent infection, in the absence of acute disease. However, infection is not completely without consequence as persistently infected rats show behavioral, emotional and cognitive impairments.

Neurological disease mediated by BoDV-1 comes in two forms: immune-mediated pathology and alterations in cell function as a direct result of viral proteins. Studies carried out in cultured cells and laboratory rodents reveal myriad effects of BoDV-1 infection at the cellular level. BoDV-1 proteins have various effects on cell signaling, apoptosis, and neurogenesis. Specific effects vary with virus isolate and cell types tested, however it is clear that BoDV-1 proteins cause significant changes in cell physiology and function. Some examples include: Up or down regulation of important signaling proteins such as PKC, Raf, MEK and ERK, changes in gene expression of (TGF)- β family members, and inhibition of histone acetylation. BoDV-1 infection of neuronal progenitor cells impairs neurogenesis and causes diminished neuritic outgrowth and synapse formation. Many of these cellular perturbations are linked to BoDV-1 P and it has been shown that expression of P in transgenic mice induces measurable behavioral abnormalities.

Diagnosis

Clinical presentation alone is insufficient for a diagnosis of bornaviral disease in animals as differential diagnosis for an animal with encephalitis will include any number of viral agents (which will vary by species). Currently there is no single assay recommended for diagnosing bornavirus infection, however a number of serological assays for detection of antiviral antibodies have been described. These include immunofluorescence assays (targeting bornavirus-infected cells) and Western blot and ELISA (targeting recombinant N or P antigens). Results of serologic assays must be interpreted carefully as a negative antibody test does not rule out bornavirus infection, as some infected animals will be antibody negative. Conversely, antibody positive animals may be completely healthy and positive serology is not a predictor of disease among healthy animals. In birds with suspected PDD, serologic assays are highly problematic as antibody production in experimentally infected birds is highly variable.

Detection of bornaviral RNA by reverse transcriptase (RT) PCR is a more reliable indicator of infection. Most PCR assays target the N or P genes. In cats, recommended samples include blood, serum, urine, conjunctival, oral, nasal and/or anal swabs. In birds, avian bornaviral RNAs can be detected in cloacal swabs and the urofeces but virus shedding is intermittent. While positive PCR results are indicative of bornavirus infection, negative results indicate only a current lack of viral shedding. Currently, PCR remains the best indicator test for avian bornavirus infection.

Bornavirus induced encephalitis is usually fatal, thus many diagnoses are made post-mortem. Typical findings include non-suppurative lymphocytic infiltrates in the brain or spinal cord. Perivascular cuffing is a common finding upon histological examination of brain tissues. Immunohistochemistry using N or P antisera can be used to stain bornavirus infected neurons to achieve a definitive diagnosis. RT-PCR of RNA extracted from brain tissue may also be used to confirm bornavirus infection.

Control and Prevention

There are currently no bornaviral vaccines approved for veterinary use in either mammals or birds. Other than among pet birds, symptomatic bornavirus infections of animals are quite rare, even in confirmed endemic areas of Central Europe. Infections in this region are likely the result of contact with urine or feces of natural hosts, such as the white-toothed shrew. Currently the highest risk of human bornavirus infection appears to be contact with certain squirrels (*S. variegatoides* and *C. prevostii*). Four human deaths from Mammalian 2 orthobornaviruses have been reported in Germany, and all occurred among persons having contact with either *Sciurus* or *Callosciurus* squirrels which are exotic to Europe. The original source of the squirrel infections is unclear but

keeping exotic squirrels as pets may be inadvisable. In 2018 two human deaths due to BoDV-1 infection were reported in Germany. These were associated with organ transplantation from a BoDV-1 infected donor. It is currently not clear if the risk of human bornavirus encephalitis is higher in Germany than in other locals, or if these cases were detected due to heightened awareness of the potential for bornavirus infection in this area. Unfortunately serologic assays will not detect 100% of bornavirus infections and even the most sensitive PCR assays will not detect virus if replication is restricted to the central nervous system. Controlling the spread of avian bornaviruses among pet birds might be achieved by testing birds using PCR assays of urofeces.

Future Prospects

Since the advent of metagenomics analyzes and high-throughput sequencing, the list of known bornaviruses has grown from 1 to 5 recognized species, geographic range has expanded from an area of Central Germany to world-wide, and hosts have expanded to include birds and reptiles. Much of our understanding of bornavirus replication and pathogenesis comes from studies of BoDV-1 and it is likely that use of well-characterized laboratory rodent models will continue to add to our knowledge base. In recent years there has been debate over a role for bornavirus involvement in human psychiatric disease. The recognition of novel bornaviruses and the development of rigorous and validated methods for assessing the infection status of patients should allow clarification of this important issue. Indeed, recent reports of bornavirus-associated fatal encephalitis in humans clearly demonstrate the ability of humans serve as spillover hosts. We currently have only a rudimentary understanding of the natural reservoirs of bornaviruses and continued surveys are needed to gain a more complete understanding of the full host range and genetic diversity of these fascinating viruses. On a very different note, the study of EBLs should be pursued as a tractable model for understanding the ancient history of the association between eukaryotes and their viruses.

Glossary

Bidirectional transcription The long terminal repeats located at the 5' and 3' ends of the provirus contain promoter sequences that direct bi-directional transcription.

Clonal expansion As a retrovirus, BLV replicates upon expression of an integrated provirus, budding of the viral particle and infection of a new cell (the infectious cycle). When integrated into the host chromosome, BLV replication

also occurs by cell mitosis through a mechanism of clonal expansion.

MicroRNA Besides genomic and subgenomic mRNAs, BLV also transcribes 10 viral microRNAs that are exported into the plasma of infected animals.

Provirus BLV is a retrovirus whose RNA genome is reverse transcribed into DNA, the provirus, that integrates into the host chromosome.

Classification

According to the International Committee on Taxonomy of Viruses (ICTV, 2019 release), BLV is classified in the *Ortervirales* order, *Retroviridae* family, *Orthoretrovirinae* subfamily and *Deltaretrovirus* genus.

Epidemiology and Clinical Features

The bovine leukemia virus (BLV) is an exogenous, oncogenic retrovirus that naturally infects B-cells of cattle (*Bos taurus*), water buffalo (*Bubalus bubalis*), yak (*Bos grunniens*) and zebu (*Bos taurus indicus*) (Meas *et al.*, 2000; Burny *et al.*, 1988). BLV-associated disease was initially observed in 1871 in an enlarged spleen of a cow (Gillet *et al.*, 2007). BLV is the etiological agent of enzootic bovine leukosis (EBL) characterized by lymphoma and lymphosarcoma (extranodular lymphoma in different organs such as eyes, heart, liver, lung, and skin) (Burny *et al.*, 1985). While most are asymptomatic carriers, a minority of infected animals develop EBL several years after infection (Barez *et al.*, 2015). The frequency of tumors and clinical latency depend on herd prevalence: a typical picture is 10% death after three years in a herd having 50% BLV prevalence.

In approximately one third of BLV-infected cows, a benign condition called persistent lymphocytosis (PL) is characterized by an excessive accumulation of B-lymphocytes in the peripheral blood (Aida *et al.*, 2013). In PL, the number of B cells can exceed that of T lymphocytes. Animals with PL have a higher risk of EBL although tumor development also occurs without persistent lymphocytosis. BLV infection is associated with immunosuppression that favors opportunistic infections (e.g., mastitis) (Suzuki *et al.*, 2013).

Diagnosis

BLV infection initiates a strong humoral and cytotoxic immune response that tightly controls viral replication (Meas *et al.*, 2000; Kabeya *et al.*, 1999; Pyeon *et al.*, 1996). Since assays based on cytotoxic T-cell responses are not robust, diagnosis is primarily based on the presence of anti-BLV antibodies in the plasma or serum. The historical agar gel immunodiffusion test (AGID) is nowadays being replaced by the enzyme-linked immunosorbent assay (ELISA) (LaDronka *et al.*, 2018; Gutiérrez *et al.*, 2009; Portetelle *et al.*, 1991). The viral antigens that elicit the best response belong to the capsid (p24) and envelope (gp51) proteins. Commercially available ELISAs have an excellent performance in terms of specificity and sensibility. The issue with these tests is their inability to discriminate between viral infection and maternally derived anti-BLV antibodies. Approximately 1–4 weeks after infection, the humoral immune response indeed produces anti-p24 and anti-gp51 antibodies that cannot be dissociated from passive immunity acquired through the colostrum

(Ferrer and Piper, 1981; Kuczewski *et al.*, 2019). This issue is solved by different PCR methods for detecting proviral sequences (e.g., end-point, real-time, nested, filter, CoCoMo and isothermal) (Jimba *et al.*, 2010; Jaworski *et al.*, 2018; Ruggiero *et al.*, 2018).

Prevention and Treatment

BLV is a major animal health problem worldwide causing important economic losses (Norby *et al.*, 2016). A series of attempts were developed to reduce prevalence, chiefly by eradication of infected cattle or segregation of BLV-free animals (Rodríguez *et al.*, 2011). The “test and eliminate” strategy requires identification of BLV-positive animals either by genomic or serological methods, removal of positive cases from the herd and slaughtering. Although having been instrumental in regions such as in Europe, this strategy was unsuccessful elsewhere mainly due to excessive costs (EFSA AHAW Panel, 2015). Since efficient transmission correlates with high proviral loads, an alternative is to identify and discard only the virus shedders. Although the impact on genetic and reproductive potential is reduced in the herd, BLV infection persists over longer periods (Ruggiero and Bartlett, 2019).

The “test and segregate” approach detects and separates BLV-infected and healthy cattle in different areas. The need of separated operational structures duplicates housing facilities and equipment, thereby excessively increasing the costs.

“Test and manage” BLV-infected and healthy animals in the same housing facilities requires permanent surveillance of the herd. This strategy is cost-effective, requires only minimal investment on facilities and does not need replacement of culled BLV-infected cattle (Bartlett *et al.*, 2014). The “Test and manage” approach is nevertheless intensively laborious, requires strict adherence to the rigorous implemented measures and needs long-term commitment to the program. Management includes the single-use of disposable material (needles, syringes and obstetrical sleeves), the disinfection of reusable surgical instruments (dehorning, tattooing, castration or ear-tagging) and elimination of hematophagous insects (Rodríguez *et al.*, 2011).

The strategies of testing and slaughtering/segregating/managing could be implemented with a treatment that limits the proviral loads. For example, valproic acid (VPA), an HDAC inhibitor, has been successfully used to reduce the PVL in leukemic sheep (Achachi *et al.*, 2005). Although VPA treatment does not clear infection, reduced PVL correlates with decreased transmission and pathogenesis.

BLV transmission can also be prevented by feeding the calves with colostrum from BLV-infected cows (Ferrer and Piper, 1981; Kuczewski *et al.*, 2019). Although anti-BLV antibodies from the colostrum efficiently prevent infection, there is a risk of transmission when plasma titers decrease.

Vaccination against BLV has been quite difficult to achieve probably because of its ability to stably integrate into the host genome, undergo long-term latency in a proportion of infected cells and thereby escape immune response. Since clearance of the virus is impossible once infection is established, the primary goal was to achieve sterilizing immunity. Besides efficacy, safety is the major issue since vaccination has been associated with increased infection or reversion to pathogenicity. After a series of failures due to the fast decline of protective antibody titers and poor stimulation of cytotoxic response, an efficient and safe vaccine is now available (Gutierrez *et al.*, 2014; Abdala *et al.*, 2019). The concept of this vaccine is to establish a permanent infection with an attenuated strain that impedes wild-type challenge by activating the anti-viral immune response. Since the vaccine strain replicates at very low levels, is not pathogenic and does not transmit to uninfected sentinels or from cow-to-calf. Moreover, the low level of replication also prevents a significant impact on the host immunocompetence, thereby avoiding immunosuppression and opportunistic infections.

Life Cycle

The infectious cycle of BLV replication initiates with the interaction of the viral particle with the cell membrane (Fig. 1). The BLV envelope glycoprotein gp51 binds to the cationic amino acid transporter 1 (CAT1)/solute carrier family 7 member 1 (SLC7A1) receptor (Bai *et al.*, 2019). The transmembrane protein gp30 then promotes fusion between the lipid bilayers of the viral and cell membranes (Willems *et al.*, 1995). Upon uncoating of the capsid, the BLV genomic RNA is reverse transcribed into a double stranded DNA provirus that is transported into the nucleus after circularization (Gillet *et al.*, 2007). Integrase-mediated proviral insertion into the host cell genome is random albeit BLV proviral integration significantly favors transcribed regions of the genome (Gillet *et al.*, 2013). Negative selection then eliminates 97% of the clones detected at seroconversion and disfavors BLV-infected cells carrying a provirus located close to a promoter or a gene. Nevertheless, among the surviving proviruses, clone abundance positively correlates with proximity of the provirus to a transcribed region. The integrated provirus can remain silent or be transcribed under the control of various stimuli (e.g., PKC, calmodulin) (Kerkhofs *et al.*, 1996). Translation of viral proteins, encapsidation of genomic RNA and budding at the cell membrane release a new infectious virion.

Besides this infectious cycle, BLV also replicates by mitosis of its host cell (i.e., clonal expansion) (Gillet *et al.*, 2013). The relative importance of these two cycles in viral replication varies during infection. The majority of infected clones are created early before the onset of an efficient immune response. Later on, the main replication route is mitotic expansion of pre-existing infected clones. The mechanism that stimulate preferred mitosis of BLV-infected cells is still incompletely understood but involves oncogenic viral proteins such as Tax and G4 (Willems *et al.*, 1990; Kerkhofs *et al.*, 1998).

Virion Structure

The BLV RNA genome is packaged in a capsid surrounded by an external envelope (Fig. 2). The p12 nucleocapsid (NC) protein is a proline-rich polypeptide that is tightly bound to the packaged genomic RNA. The p24 protein is the major constituent of the capsid

Fig. 1 Schematic representation of the two modes of BLV replication. (A) In the infectious cycle, the virion enters the cell by envelope-mediated membrane fusion. After reverse transcription of the genomic RNA, the provirus integrates into the host chromosome. Upon transcription of the provirus and translation, viral proteins and genomic RNA form a virion that buds out of the cell (B) An infected cell harboring an integrated provirus undergoes mitosis. Further proliferation generates a population of cell clones characterized by a single proviral integration site.

Fig. 2 Structure of the BLV virion. Env, Gag and Pro-Pol proteins are indicated by orange, blue and green arrows. Gag = group-specific antigen; Env = envelope; MA = matrix; NC = nucleocapsid; CA = capsid; PRO = protease; RT = reverse transcriptase; IN = integrase; SU = extracellular envelope protein; TM = transmembrane protein.

Fig. 3 Schematic representation of an integrated BLV provirus, viral RNAs and proteins. The long terminal repeats (LTR in green) flank the viral genes (in gray). The provirus is integrated into chromatin. Sense and antisense transcripts are colored in blue and purple, respectively. GAG = group-specific antigen; ENV = envelope; miR = viral microRNAs; premiR = precursor microRNA; U3 = unique 3' end; R = redundant region; U5 = unique 5' end; PPT = polypurine tract; PBS = primer binding site; ψ = packaging Psi sequence; AS1-S = antisense 1 short; AS1-L = antisense 1 long; AS2 = antisense 2; pr = precursor; p = protein; gp = glycoprotein; MA = matrix; NC = nucleocapsid; CA = capsid; PRO = protease; RT = reverse transcriptase; IN = integrase; SU = extracellular envelope protein; TM = transmembrane protein. Numbers are coordinates according to the GenBank AF033818.1 reference genome (1 is the transcription initiation site).

(CA) of BLV virions and a major target for the host immune response. The matrix (MA) protein p15, which corresponds to the NH₂-terminal end of the gag precursor, is a myristylated and phosphorylated polypeptide. MA proteins bind the genomic viral RNA but also interact with the lipid bilayer of the viral membrane. The Gag proteins (MA, CA and NC) are derived from the proteolytic cleavage of the Pr44gag precursor carried out by the viral protease p14 (PRO). The BLV virion also contains two enzymes required to reverse transcribe the RNA genome into proviral cDNA (RT) and for its integration into the chromosome (IN). Finally, the capsid is surrounded by an envelope of cellular and viral origin. The extracellular gp51 (SU) and the transmembrane gp30 (TM) proteins are glycosylated polypeptides that associate through disulfide bonds. TM is embedded through a lipid bilayer acquired upon budding from the cell membrane. Insertion, in an oblique orientation, of the N-terminal fusion peptide of TM into the lipid bilayer of a target cell promotes cell fusion and viral entry. SU is involved in receptor binding and cell fusion.

It should be emphasized that, although BLV virions are spontaneously expressed in ex vivo cultures from peripheral blood mononuclear cells (PBMCs), there is no viremia in infected animals, likely due to a very efficient immune response.

Genome Organization and Expression

The BLV provirus integrated into chromatin is schematized in **Fig. 3**. The genome contains the classical gag-pro-pol-env structural and enzymatic genes required to produce the viral particle. As a delta-retrovirus, BLV also harbors 4 genes (Tax, Rex, R3 and G4) involved in different regulatory mechanisms (see the paragraph on pathogenesis). A series of non-coding RNAs are transcribed from a microRNA cluster (miRs) and in an antisense orientation (AS1-S, AS1-L, AS2). The provirus is flanked by two identical long terminal repeats (5'LTR and 3'LTR) that direct initiation and termination of transcription.

The U3-R boundary of the 5' LTR identifies the transcription initiation site of the sense RNAs (**Fig. 3**). Transcription terminates by polyadenylation at the R-U5 junction of the 3'LTR. Sense transcription is initiated by a TATA box (GATAAT) and controlled by a series of enhancers. Among these, three 21 bp-long Tax-responsive elements (TxREs) contain imperfectly conserved cyclic-AMP responsive elements (AGACGTCA; TGACGGCA and TGACCTCA). These enhancers mediate activation of transcription by the viral Tax protein upon interaction with CREB/ATF (*Calomme et al., 2004; Adam et al., 1994*) (**Fig. 4**). Other regulators of sense transcription include binding sites for NF- κ B, PU.1/Spi-B, glucocorticoid responsive element (GRE), E box and interferon regulatory factor (IRF) (see review (*Gillet et al., 2007*) for further details).

The genomic RNA contains the Psi site (ψ) required for its packaging inside the virion and the tRNA primer-binding site (PBS) that is involved in initiation of reverse transcription. During reverse transcription, an RNA polypurine tract (PPT) resists digestion by RT and primes plus-strand DNA synthesis. The genomic RNA is capped with 7-methyl guanosine and is spliced into 4 transcripts (*env*, *tax/rex*, *R3* and *G4*).

The RT and IN proteins are translated from a 145-kDa polypeptide via a frameshift mechanism of the gag-protease precursor (pr66gagprt). Different Gag proteins (MA, CA and NC) are derived from the proteolytic cleavage of the Pr44Gag precursor. This post-translational maturation is carried out by the viral protease PRO (p14) that is encoded by a region located between the *gag* and the *pol* genes. p14 is synthesized from a Gag-protease precursor (pr66GagPrt) via a frameshift suppression of the gag termination codon by a lysine-specific tRNA.

The sequences coding for the envelope partially overlap in a different frame the 3' end of the *pol* gene by 51 nucleotides (**Fig. 3**). A single-spliced RNA encodes the pr72Env precursor that is cleaved into gp51 (SU) and gp30 (TM) by the subtilisin/kesin-like convertase furin. The SU and TM glycosylated proteins associate through disulfide bonds and interact with the cell membrane.

Fig. 4 Regulatory elements of the LTR promoter. Transcription of the 5'-LTR is initiated by RNAPII at position +1. TxRE = Tax responsive element; CRE = cyclic-AMP response element; GRE = glucocorticoid responsive element; E-box = enhancer box; NF- κ B = nuclear factor κ B; TATA = TATA box; IRF = interferon regulatory factor; U3 = unique 3' end; R = redundant region; U5 = unique 5' end. All coordinates are indicated according to the GenBank: AF033818.1 reference genome.

Among regulatory proteins, Tax is a phosphoprotein that activates directed transcription via CREB/ATF and TxRE elements located in U3 (Willems *et al.*, 1987, 1998) (Fig. 4). Tax is oncogenic in immortalization assays in primary cells and in mouse models (Willems *et al.*, 1990), a property that is shared with G4 (Kerkhofs *et al.*, 1998). Localized in the mitochondria and the nucleus, the G4 protein interacts with farnesyl pyrophosphate synthetase (FPPS) involved in the mevalonate/squalene pathway and prenylation of Ras (Lefebvre *et al.*, 2002). The role of nuclear R3 protein is still unclear but could pertain to regulation of Rex activity. The 18 kDa Rex nuclear phosphoprotein interacts with the RxRE responsive RNA element located between the AATAAA polyadenylation signal and the polyadenylation site (8156–8420) of viral transcripts (Derse, 1988). p18 mediates splicing and is required for the accumulation of viral genomic and env transcripts. Tax and Rex are essential genes while R3 and G4 are dispensable for infectivity (Willems *et al.*, 1994; Florins *et al.*, 2007b).

BLV also transcribes two antisense RNAs (AS1 and AS2) initiating at two transcriptional start sites of an active RNAPII promoter located in the 3' LTR (Van Driessche *et al.*, 2016; Durkin *et al.*, 2016). The AS1 RNA is differentially polyadenylated, generating AS1-L (2200 bp) and, more abundantly, AS1-S (600 bp) (Fig. 3). The AS1-L isoform overlaps the microRNA cluster and is therefore cleaved in the cytoplasm by the RISC complex. The antisense transcripts are predominantly located in the nucleus and are predicted to be untranslated. Their possible role as long non-coding RNAs mediating mechanisms such as epigenetics remains to be determined.

Finally, five precursor miRNAs are transcribed from a cluster located 3' of the env gene on the BLV genome (Rosewick *et al.*, 2013; Kincaid *et al.*, 2012) (Fig. 3). The pre-miRNAs are directly transcribed from RNA polymerase III (RNAPIII) promoters and are further processed in the cytoplasm into 10 mature miRNAs by Dicer (Fig. 5). The pre-miRNAs are therefore not processed by the Drosha enzyme, but still largely depend on the DUSP11 phosphatase and Dicer (Burke *et al.*, 2016). In contrast to genomic and subgenomic RNAs, miRNAs are abundantly expressed in infected animals (i.e., up to 40% of all detected cellular miRNAs) (Rosewick *et al.*, 2013; Gillet *et al.*, 2016). Mechanistically, the BLV miRNAs target genes involved in proliferation, oncogenesis, cell signaling, apoptosis and immunity (e.g., GZMA, FOS, PPT1, ANXA1, MAP2K1 and PIK3CG) (Gillet *et al.*, 2016). Deletion of the miRNA cluster reduces viral replication in the natural (bovine) and experimental (ovine) models. Ablation of miRNAs mainly affects proliferation and abolishes pathogenesis in BLV-infected sheep (Safari *et al.*, 2020).

It thus appears that BLV proviral transcription is characterized by a complex profile of miRNAs, sense and antisense RNAs driven by RNAPII and RNAPIII, respectively.

Pathogenesis

Although the mechanisms associated with BLV pathogenesis still need to be further investigated, a series of experimental results generates a hypothetical but consistent model (Safari *et al.*, 2017; Gazon *et al.*, 2018; Florins *et al.*, 2007a). The hypothesis is based on a tight equilibrium between a virus attempting to proliferate and an infected host that develops an efficient immunity to control viral replication. Evidence includes the following:

- (1) Despite a strong anti-viral immune response, BLV persists indefinitely throughout life;
- (2) BLV encodes oncogenes promoting cell proliferation and transformation (Kerkhofs *et al.*, 1998; Twizere *et al.*, 2003);
- (3) Expression of structural (*gag*, *env*), enzymatic (*pol*) and regulatory (*tax*, *rex*, *R3* and *G4*) genes is barely detectable in vivo (Lagarias and Radke, 1989);
- (4) Viral miRNAs expressed abundantly in cells and in plasma are required to maintain high proviral loads (Rosewick *et al.*, 2013; Gillet *et al.*, 2016);
- (5) Non-coding antisense transcripts are silent to the immune response and may affect epigenetics (Durkin *et al.*, 2016);
- (6) BLV integrates randomly but favors transcriptionally active sites nearby cancer drivers (Gillet *et al.*, 2013; Rosewick *et al.*, 2017);
- (7) Forced proliferation of infected cell clones generates replication-associated mutations that are predicted to drive oncogenicity (Rosewick *et al.*, 2017);
- (8) Persistent infection induces inflammation and immunosuppression (Pyeon *et al.*, 1996; Konnai *et al.*, 2013)
- (9) The host's genetic background and viral determinants affect proviral loads (de Brogniez *et al.*, 2015; Willems *et al.*, 2000; Hayashi *et al.*, 2017; Tajima and Aida, 2000; Takeshima *et al.*, 2017)
- (10) Host immunity tightly controls viral replication (Florins *et al.*, 2006; Florins *et al.*, 2009; Florins *et al.*, 2011; Frie *et al.*, 2018)

Regular switches between 5' and 3' transcription may allow transient Tax expression and fast silencing of viral expression. Associated with viral miRNAs, this mechanism would allow Tax-driven cell proliferation and synthesis of viral particles in presence of the host immunity. This model thus illustrates the dynamic equilibrium between a virus attempting to proliferate under a tight control exerted by the immune response.

Bovine Viral Diarrhea, Border Disease, and Classical Swine Fever Viruses (*Flaviviridae*)

Paul Becher and Volker Moennig, University of Veterinary Medicine, Hannover, Germany
Norbert Tautz, University of Luebeck, Luebeck, Germany

© 2021 Elsevier Ltd. All rights reserved.

Classification

Bovine viral diarrhea virus 1 (BVDV-1), BVDV-2, Border disease virus (BDV) and Classical swine fever virus (previously called *Hog cholera virus*) belong to the genus *Pestivirus* within the family *Flaviviridae*. In addition, a growing number of additional pestiviruses has been identified from various hosts of the order *Artiodactyla* including pig, cattle, sheep, goat, wild boar, giraffe, Pronghorn antelope, and various other wild ruminant species. More recently, distinct pestivirus sequences have been detected in samples from several rodent and bat species. These viral sequences significantly differ from artiodactylous pestiviruses and form two separate clusters. The recently identified atypical porcine pestivirus (APPV) which causes congenital tremor in newborn piglets is most closely related to pestiviruses from bats. Taken into account the growing number and the expanded host range of genetically highly variable pestivirus species, the *Flaviviridae* study group of the International Committee on Taxonomy of Viruses (ICTV) has proposed a revision to the taxonomy of the genus *Pestivirus*. This included the modification of the criteria for pestivirus species demarcation, the creation of seven additional new pestivirus species and naming species in a host-independent manner using the format *Pestivirus X*. This revision is consistent with the recently revised format used for the genera *Hepacivirus* and *Pegivirus* of the *Flaviviridae* family. BVDV-1, BVDV-2, CSFV, and BDV are termed *Pestivirus A*, *Pestivirus B*, *Pestivirus C*, and *Pestivirus D*, respectively. The seven additional pestivirus species (with reference viruses or previously used designations provided in parentheses) are *Pestivirus E* (pronghorn pestivirus), *Pestivirus F* (Bungowannah virus), *Pestivirus G* (giraffe pestivirus), *Pestivirus H* (Hobi-like pestivirus), *Pestivirus I* (Aydin-like pestivirus), *Pestivirus J* (rat pestivirus) and *Pestivirus K* (atypical porcine pestivirus) (Fig. 1). The proposed changes only relate to the nomenclature of virus species names, while virus isolates and established pestiviruses are still referred to their original names. Pestiviruses identified from pigs (Linda virus), sheep (MG770617, MK618726), sheep and goat (Tunisian sheep pestivirus, not included in Fig. 1) as well as from bats, rodents and whales (not included in Fig. 1) may represent additional species (Fig. 1). Demarcation of pestivirus species is based on sequence relationships and antigenic relationships, and is frequently associated with differences in host range and diseases caused by these viruses. For the bat and rodent pestiviruses, virus isolates are not available and therefore antigenic relationships have not been studied.

Phylogenetic analyses of complete and partial genomic sequences revealed that CSFV, BVDV-1, BVDV-2, and BDV can be further segregated into defined genotypes and subgenotypes. The genetic variations identified in individual virus isolates may be implicated in disease control. It has been reported that vaccines and diagnostics that work well against homologous virus strains can be less efficacious for genetically different viruses. Moreover, genetic typing of CSFV and BVDV isolates can improve the understanding of epidemiological relations between outbreaks and may assist in tracing the source of disease outbreaks.

CSFV can be divided into at least three major genotypes (1, 2 and 3), each comprising three to seven subgenotypes (1.1–1.7; 2.1–2.3; 3.1–3.4). Recent studies suggested that the genetic diversity of CSFV might be broader than previously reported and proposed up to seven subgenotypes within genotype 2. For assignment of newly identified CSFV isolates to a (sub)genotype, either full-length genomic sequences or partial sequences have to be determined and subsequently compared to the available sequences of other known CSFV isolates. In addition to full-length genomic sequences, complete E2 coding sequences provide a solid basis for phylogenetic analysis and assignment to a defined subgenotype. More than 500 complete E2 coding sequences are available for CSFV. Compared to BVDV-1 and BDV, the genetic variability of CSFV is lower. During long lasting epidemics, only a very limited number of nucleotide changes have been observed.

BVDV-1 can be segregated into at least twenty-one subgenotypes (BVDV-1a-1u), while four subgenotypes have been described for BVDV-2. Epidemiological studies have demonstrated that various BVDV subgenotypes predominate in different countries and geographic regions. For BDV at least eight distinct and highly variable genotypes have been reported. Future investigations of BVDV-1, BVDV-2, BDV, and CSFV isolates may result in the identification of additional genotypes and subgenotypes.

Genome Structure and Polyprotein Processing

The pestiviral genome is a single-stranded RNA with a length of about 12.3 kb but naturally occurring virus mutants with genomes up to 16.5 kb have been described. The single large open reading frame (ORF) is flanked on both ends by untranslated regions (UTRs). The 5'UTR folds into a complex structure which is critical for RNA replication and the formation of an internal ribosome entry site (IRES) mediating internal initiation of translation. In the 3'UTR, which also contains structural RNA elements of functional importance for viral RNA replication, highly conserved binding sites for the small cellular RNAs miR-17 and let-7 have been identified. Binding of these RNAs increases genome stability and stimulates translation.

The polyprotein consists of approximately 3900 amino acids and is co- and posttranslationally processed by host- and virus-encoded proteases into 12 mature proteins. However, also cleavage intermediates play a crucial role in the pestiviral life cycle. The organization of the polyprotein is NH₂–N^{pro}/C/E^{ms}/E1/E2/p7/NS2/NS3/NS4A/NS4B/NS5A/NS5B–COOH (Fig. 2). The first protein encoded in the ORF is the N-terminal protease (N^{pro}) which cleaves off itself from the remainder of the polyprotein

Fig. 1 Phylogenetic relationship of pestiviruses. Phylogenetic trees were constructed using MEGA 6 and based upon distances between amino acid sequences for amino acid positions 3312–3899 (NS5B region) by maximum likelihood using a JTT + G model as recommended by the Flaviviridae Study Group of the International Committee on Taxonomy of Viruses (ICTV). Accession numbers of the individual sequences allocated to the eleven established pestivirus species (*Pestivirus A-K*) or representing tentative pestivirus species (Ovine MG770617 and Ovine MK618726, Linda KY436034, Bat MH282908 and Rodent KY370100; highlighted by astrisks) are indicated. Up to 6 sequences were used for each species. Numbers indicate branches supported by >70% of bootstrap replicates. The authors thank Gökçe Nur Cagatay, University of Veterinary Medicine Hannover, Germany, for providing the phylogenetic tree.

thereby generating the N terminus of the core protein (C). The cleavages required for the release of the structural proteins C, E^{rns}, E1 and E2 as well as p7 are mediated by the cellular signal peptidase residing in the ER. The C terminus of C is further processed by cellular signal peptide peptidase. NS2 acts as an autoprotease generating its own C terminus and thereby the N terminus of NS3. NS3 is multifunctional with proven protease, helicase and NTPase activities. NS3 is believed to generate autocatalytically its own C terminus. For full protease activity NS3 forms a complex with its cofactor NS4A which intercalates with one beta-strand into the protease domain of NS3. The NS3/4A complex catalyzes all cleavages further downstream in the polyprotein.

Virion Structure

The virions of pestiviruses are enveloped and have a size of about 50 nm (**Fig. 3**). Early immuno-EM studies using monoclonal antibodies against E^{rns} and E2 have shown for CSFV and BVDV the presence of both proteins at the surface of the virion. Already in

Fig. 2 Pestivirus genome organization. The genomic RNA contains one open reading frame flanked by 5' and 3' nontranslated regions (NTR). The proteinases involved in polyprotein processing are indicated. *H*, helicase; *RdRp*, RNA-dependent RNA polymerase. Modified from Becher, P., Thiel, H.J., 2011. Pestivirus. In: Tidona, C., Darai, G. (Eds.), The Springer Index of Viruses. Springer Science + Business Media, LLC. doi:10.1007/978-0-387-95919-1.

Fig. 3 Extracellular virions on MDBK cells infected with giraffe pestivirus (Pestivirus G), 15 h p.i., bar: 100 nm. Reproduced with permission from Schmeiser, S., Mast, J., Thiel, H.J., König, M., 2014. Morphogenesis of pestiviruses: New insights from ultrastructural studies of strain Giraffe-1. Journal of Virology 88, 2717–2724.

those studies E^{ns} was preferentially detected. A more recent, detailed structural and biochemical analysis of purified BVDV virions revealed a generally low envelope protein content with E^{ns} being more abundant than the other envelope proteins. The averaged image of the virions did not show glycoprotein spikes even after acidification of the sample, indicating that these proteins may not form a regular structure at the virion. Alternatively, those structures are not visualized due to their low abundance. The envelope proteins detected in the virions were covalent E^{ns} homodimers as well as E1/E2 heterodimers but hardly any monomers or E2 dimers. Even though the virions bud from the endoplasmatic reticulum (ER), their lipid composition differed from the one of the ER membrane indicating lipid-sorting during virion morphogenesis. In contrast to hepatitis C virus (HCV), the virions of pestiviruses showed no apolipoprotein association.

While E2 is the receptor binding protein and most neutralizing antibodies are directed against this component of the virion, a limited degree of neutralization was also observed for antibodies against E^{ns}. Structural information for E2 of BVDV has been obtained in two studies. These structures revealed no similarity of E2 to the class II fusion proteins of the alphaviruses or members of the genus *Flavivirus*. Therefore, it remains to be finally determined whether E2 or E1, the least well investigated glycoprotein of pestiviruses, act as fusion protein in the process of cell entry.

A duplication of the core protein as well as fusions of core with YFP (yellow fluorescent protein) did not lead to abrogation of virion morphogenesis. Surprisingly, even the deletion of C could be partially compensated by single mutations located in the C-terminal region of NS3. Taken together, the enormous flexibility of C with respect to formation of infectious virions may indicate that C does not form a rigid icosahedral structure in the virion but acts as an RNA binding protein with a potential RNA chaperone activity. This assumption is further corroborated by the fact that pestiviral genomes with massively increased genome size can still be efficiently packaged into infectious viral particles. For a final clarification of the architecture of the pestiviral capsids, a high resolution structure will be required.

E^{ns} is unique to pestiviruses and its most unusual feature is its RNase activity. Structural analysis further verified the postulated similarity to T2 RNases. The RNase activity is neither required for the infectivity of the virion nor for viral replication in cell culture. However, inactivation of the RNase led to an attenuation of BVDV in its natural host. Besides being part of the infectious virion, E^{ns} is also present in significant amounts in the serum of infected animals. Detailed analyses have shown that an unusual in plane membrane anchor is critical for the shedding of E^{ns} from infected cells. This alpha-helix also seems to play a distinct role in the formation of infectious viral particles. Furthermore, E^{ns} was shown to act as an antagonist of the innate host response to infection. In cell culture experiments E^{ns} was able to suppress the induction of interferon- β and interferon-induced protein expression after stimulation by extracellular dsRNA or ssRNA. The RNase activity of E^{ns} is required for its immunosuppressive effect. Secreted E^{ns} can bind to cells, be taken up by Clathrin-dependent endocytosis and interfere with IFN induction by extracellular dsRNA. Viral RNA shedded from pestivirus infected cells, most likely via exosomes, was shown to induce IFN secretion by plasmacytoid

dendritic cells (PDCs). This stimulation of PDCs could be antagonized by E^{ms} via an RNase-dependent mechanism. For the *in vivo* function homodimerisation of E^{ms} via a disulfide bridge seems to be of importance since a strong positive selection for the cysteine critical for dimerization has been observed. The cleavage of ss or dsRNA by E^{ms} does, however, not depend on its dimerization.

Pestiviral Nonstructural Proteins and the Regulation of RNA Replication and Virion Morphogenesis

N^{pro}

N^{pro} is the only viral protein dispensable for RNA replication and virion morphogenesis. However, it is one of the major repressors of Interferon-1 (IFN-1) induction in pestivirus infected cells. Recently the crystal structures for N^{pro} of a HoBi-like BVDV-3 strain and of CSFV strain Alfort 187 were reported. These studies did finally prove that the protease activity is based on a catalytic diad composed of His49 and Cys69. Moreover, the structural information depicted that the C terminus of N^{pro} is locked into the catalytic site after autocleavage, thereby disabling any trans-cleavage activity of this enzyme. In line with these findings, the protease activity of N^{pro} is not required for the suppression of IFN-1 response. N^{pro} interacts directly with interferon regulatory factor 3 (IRF3), one of the major transcription factors responsible for the transcription of IFN- α/β mRNA. For this interaction a structurally important TRASH motif coordinating a Zn ion, is essential. N^{pro}/IRF3 interactions finally lead to an ubiquitin-dependent proteasomal degradation of IRF3 which strongly interferes with the induction of an IFN- α/β response in pestivirus infected cells.

p7

The small hydrophobic protein p7 in part remains uncleaved at the C terminus of E2 while most p7 gets released by signal peptidase cleavage. p7 is so far not detected in virions and thus classified as nonstructural protein. The E2-p7 precursor is not essential for the viral life cycle, at least in cell culture. Due to its sequence characteristics a viroporin function was postulated for p7 and finally demonstrated. Together with results obtained by studying p7 of HCV the ion channel activity of p7 may be required to protect immature intracellular virions from inactivation by acidification. In addition to its viroporin function, p7 may be involved in critical protein/protein interactions during virion morphogenesis as observed in the HCV system.

NS2

NS2 has a length of about 450 amino acids and thus about twice the size of NS2 of HCV. NS2 is composed of a hydrophobic N-terminal half anchoring the protein to membranes and a C-terminal protease domain with a putative structural Zn-binding site residing in the cytoplasm. However, so far neither the membrane topology nor the structure of the protein has been clarified. The activation of the cysteine protease domain requires an interaction with the cellular chaperone DNAJC14 to become active thereby releasing itself from NS2-3. The finding that NS2 becomes only active for cleavage *in trans* after C-terminal truncation suggests that the C terminus of the protein remains after autocleavage in the active site rendering the cleavage product enzymatically inactive. Actually, the crystal structure of the HCV NS2 autoprotease revealed such an autoblockade, which is also described above for N^{pro}. At the moment no function of the released NS2 has been identified. However, in the context of NS2-3 the NS2 part plays an essential role in virion morphogenesis (see below).

NS3

NS3 is an essential component of the viral replicase which can't be functionally complemented by uncleaved NS2-3. It is a multifunctional protein with an N-terminal serine protease domain and a helicase/NTPase domain connected by a flexible linker. The crystal structure of a single chain NS3-4A protease of CSFV verified that, analogous to findings from the HCV system, NS4A intercalates with its central peptide into the beta-barrel domain of the NS3 protease. Mutations based on the closed conformation structure of CSFV NS3/4A revealed a critical role for the interaction between helicase and protease domain in RNA replication. Only in complex with NS4A the NS3 protease gains its full protease activity and can process e.g., the NS5A/B site. Interestingly, for NS3/4A a surface interaction between NS3 and the part of NS4A located downstream of the central peptide could be visualized in the crystal structure. Mutagenesis studies demonstrated that inactivation of protease, helicase or NTPase function of NS3 interferes with viral RNA replication. For the most C-terminal part of NS3, namely helicase subdomain 3 a surprising compensatory role in CSFV variants with a core deletion was described. Single amino acid exchanges were able to partially rescue the core deletion variants with respect to virion morphogenesis. However, those viruses were attenuated in their natural host. These findings raise the question whether this domain may also be involved in virion morphogenesis in wild type pestiviruses, especially since in this virus system all nonstructural proteins, besides N^{pro}, are required for this process. In this context it is remarkable that the members of the genus *Pegivirus* do not encode a core protein, but still produce infectious progeny. Moreover, also for other members of the *Flaviviridae* family mutations located in the helicase were able to rescue virion morphogenesis deficiencies.

NS2-3

Cleavage of NS2-3 is mediated by the autoprotease in NS2. Since NS3 but not NS2-3 is an essential component of the viral replicase the release of NS3 is of regulatory importance for viral RNA replication efficiency. The NS2 autoprotease depends in its activity on the stable interaction with DNAJC14. This chaperone is available only in low amounts in part due to the existence of an upstream ORF in the mRNA. Accordingly, NS2-3 produced at early times after infection will form a complex with DNAJC14 leading to activation of the NS2 protease and NS3 release. However, when translation of the viral polyproteins proceeds, NS2-3

translated at later time points will not be able to recruit DNAJC14 from the depleted intracellular pool and therefore will not undergo cleavage. Since NS3 is an essential component of the viral replicase this mechanism leads to a temporal downregulation of viral RNA replication which has been shown to be required for the noncp biotype of pestiviruses which is in turn a prerequisite for viral persistence in the animal. A shRNA-mediated knock down of the DNAJC14 mRNA in MDBK cells severely reduced the titers of BVDV-1. However, with this approach no conclusive data were obtained for other pestivirus species. By generating bovine and porcine DNAJC14 knock-out cells it was finally possible to prove that the replication of 6 distinct noncp pestivirus species, namely species A-D, F and G strictly depends on DNAJC14. Furthermore, this study allowed the conclusion that all cytopathogenic pestiviruses which are often products of RNA recombination replicate independent of DNAJC14. Those viruses are characterized by an overexpression of NS3 which is correlated with upregulation of viral RNA synthesis and cytopathogenicity.

NS2-3 is a cleavage intermediate in polyprotein processing. A product-precursor relationship between NS3 and NS2-3 was observed for the noncp CSFV strain Alfort Tübingen. Incomplete cleavage results from DNAJC14 deprivation in the infected cells (see above). In all cells infected with noncp pestiviruses significant amounts of uncleaved NS2-3 are detected. This fact is in line with the observation that uncleaved NS2-3 is essential for the process of virion morphogenesis. This function of NS2-3 became apparent when ubiquitin was inserted between NS2 und NS3 in the context of an infectious cDNA clone of BVDV-1 strain NADL. In such a polyprotein cellular ubiquitin specific C-terminal hydrolases process the C terminus of ubiquitin resulting in complete cleavage of NS2-3 which correlated with a defect in virion morphogenesis. An analogous result was obtained for a virus mutant with an IRES insertion between the sequences coding for NS2 and NS3. These findings could be reproduced for CSFV. The latter study revealed that virion morphogenesis of these mutants could be rescued by authentic NS2-3/4A complexes supplied *in trans*, in which, however, none of the enzymatic activities of NS2 or NS3 was required.

When a cell culture system for HCV became available similar studies led to the surprising result that virion morphogenesis of HCV does not depend on uncleaved NS2-3. This finding inspired research on pestiviral gain of function mutants capable of virion production in the absence of uncleaved NS2-3 which mimics the situation in the HCV system. These studies led to the identification of two gain of function mutations, one in NS2 and one in NS3 which were able to compensate the loss of virion morphogenesis due to an ubiquitin-insertion between NS2 and NS3 in BVDV. These mutants and the structural information obtained by the crystal structure of a NS3-4A single chain protease were used to address the question how NS3/4A complexes are functionalized for either RNA replication or virion morphogenesis. Reverse genetics and biochemical studies revealed that a surface interaction between NS3 and the C-terminal part of NS4A (kink region) is decisive whether a NS3/4A complex functions as a basic building block for viral replicase assembly or in the pathway of virion morphogenesis. Further studies are needed to understand those pathways in more detail.

NS4A

NS4A is a small protein which acts in the NS3/4A serine protease complex as protease cofactor. The central domain as well as the kink domain are required for the stimulation of the NS3 protease activity. The N-terminal transmembrane domain of NS4A serves as membrane anchor for the NS3/4A complex. *Trans*-complementation studies demonstrated that NS4A is also involved in virion morphogenesis. Surface interactions between NS4A and NS3 further functionalize the protein (see above).

NS4B

NS4B is a hydrophobic protein of about 35 kDa which is essential for RNA replication. However, structure and function of NS4B are largely unknown. Recently, a unique ER-like localization was described for NS4B of CSFV. In the N-terminal region of NS4B an amphipathic α -helix structure was determined which serves as membrane anchor. Mutations in this protein region could be correlated with RNA replication efficiency and virulence of CSFV. For mutations in a sequence motif indicative of an NTPase no conclusive *in vivo* data were obtained with respect to CSFV replication and virulence.

NS5A

NS5A is a phosphoprotein with a size of about 58 kDa. It is anchored to membranes via an N-terminal amphipathic α -helix. A three domain structure with intervening low complexity sequences (LCS) was postulated for NS5A of BVDV. Domain I is essential for RNA replication and contains a structural Zn-binding motif. The downstream LCS I and domain II were more tolerant to deletions/insertions leading to the establishment of a reporter replicon with a mCherry-insertion in this part of the protein. Using those replicons BVDV NS5A was found to localize to lipid droplets, an analogy to the HCV system. NS5A is so far the only replicase component that can be complemented *in trans*. For NS5A a direct interaction with and a regulatory effect on NS5B has been described and relevant amino acids have been identified. Interestingly, those residues were found to be conserved between pestiviruses and HCV.

NS5B

NS5B has RNA-dependent RNA polymerase (RdRp) activity. However, for replication of the viral RNA *in vivo* at least viral proteins NS3 to NS5B are required. The RdRp activity of NS5B can be stimulated by GTP and is capable of starting *de novo* RNA synthesis. Structural information has been obtained for NS5B of BVDV and more recently also for CSFV. The crystalized CSFV NS5B structure included a novel N-terminal domain. NS5B of BVDV has also been shown to be involved in virion morphogenesis.

Life Cycle

Cell culture studies have shown that pestiviruses attach via E^{tns} to heparan sulfate and use pH-triggered clathrin-mediated endocytosis for cell entry. Since pestiviruses are acid resistant, an additional activation step was postulated. CD46 was identified as receptor for BVDV-1 with E2 as viral interaction partner. However, expression of bovine CD46 did not confer susceptibility to non-susceptible cell lines indicating the existence of critical co-receptors. Remarkably, direct cell to cell transmission was described for BVDV even in the presence of neutralizing antibodies directed against E2. CD46 is dispensable for this process, which still employs clathrin-mediated endocytosis. Cell to cell spread may also be involved in the transmission of noncp pestiviruses over the placenta, which is required for establishing viral persistence in the fetus. For CSFV a Caveolar-dependent uptake into Alveolar macrophages has been reported involving Rab5, Rab7, and Rab11. Thus different entry pathways may be used depending on the cell type. Replication and virion formation are believed to take place at ER-derived membranes. Co-localization of the viral core protein and the envelope glycoprotein E2 with the ER marker protein disulfide isomerase (PDI) was demonstrated by immunogold labeling of cryosections while NS5A was found by *in vivo* imaging at lipid droplets which also reside in close proximity to the ER. The efficiency of RNA replication is regulated via the extent of NS2-3 cleavage (see above) and correlates with the two biotypes observed in cell culture. While the noncp biotype is capable of persistence, the cp biotype produces higher amounts of intracellular RNA which correlates with viral cytopathogenicity, rendering this biotype incompetent for establishing persistent infections. Intracellular virions were found during exocytosis in transport vesicles and the Golgi apparatus. Significant titers of infectious particles are released at about 12 h post infection. The detection of core and double-stranded RNA in multi vesicular bodies may be an indication for an involvement of the endosomal sorting complexes required for transport (ESCRT) machinery in virion budding and secretion.

Epidemiology

Classical Swine Fever

The natural hosts of CSFV are domestic pigs and wild boar (*Sus scrofa ferus*). In endemic situations CSFV can be transmitted between domestic pigs and wild boar and vice versa. Other members of the *Suidae* family like common warthogs (*Phacochoerus africanus*) and bushpigs (*Potamochoerus larvatus*) are also susceptible to infection with CSFV. For a long time, it was commonly accepted that cattle can be infected with CSFV only under experimental conditions, while a recent report suggested the occurrence of natural CSFV infections of cattle in China. The significance of CSFV infection in cattle and, possibly, other ruminants remains to be elucidated.

CSF is still endemic or sporadically occurs in large parts of the world. According to recent official reports to the OIE (since 2014), CSF is still present in China, Russia, South-East Asia, the Caribbean as well as several countries of South-America. While the African continent has no official OIE status for CSF, recent reports suggest the presence of the disease in at least some regions (e.g., Madagascar). A complete list of currently CSF-free countries is published by the OIE. Other regions of the world including Australia, New Zealand, United States of America, and Canada have been CSF-free for at least forty years. In the European Union (EU) there were only a few sporadic outbreaks of CSF in the Eastern parts of the EU during the past ten years. The last CSF outbreaks in the EU occurred in Lithuania (2009, 2011) and in Latvia (2012–2015).

A detailed knowledge of the different routes of transmission is of particular importance to understand the epidemiology of CSF and to implement suitable and efficient control measures for eradication of the disease, surveillance and maintenance of a CSF-free status. CSFV can be transmitted by horizontal and vertical routes. Infected pigs shed high titers of infectious virus via saliva, lacrimal secretions, feces, urine, and semen. Meat, blood and other products of infected pigs can also contain high viral loads. After introduction into a pig farm CSFV spreads by direct contact. These horizontal infections mainly occur through the oronasal route. Spread of CSFV within a herd or within a wild boar population progresses rather slowly. Consequently, the disease may remain unrecognized for long time periods after introduction of CSFV into a holding. The occurrence of less virulent CSFV strains during the past decades is another important factor contributing to longer high risk periods. In addition to direct contact between infected and susceptible animals, CSFV can be efficiently transmitted via contaminated materials (e.g., cloth, shoes, vehicles, agricultural and veterinary equipment) and contaminated food and waste. While swill feeding is prohibited in most countries with industrial pig production, it still represents a common practice for feeding of backyard pigs in large parts of the world. The (illegal) import of virus-contaminated food represents a major threat for introduction of the disease in CSF-free countries. The recent re-occurrence of CSFV in Japan (2018) after 26 years of absence provides an illustrative example how easy CSFV can be introduced even in a country with high biosecurity measures and subsequently can spread among domestic pigs and wild boar populations.

Vertical transmission of CSFV from pregnant sows to fetuses can occur throughout all stages of gestation and can result in the birth of persistently infected offspring. These persistently infected pigs shed the virus continuously or intermittently for the rest of their life and represent a permanent source for transmission of CSFV to susceptible animals of the same herd or to other pig holdings. The occurrence of persistently infected offspring is also known for wild boar and together with the decreased virulence of CSFV observed during the past decades may be implicated in the establishment of endemic situations in wild boar populations representing a constant risk of virus transmission to domestic pigs.

Bovine Viral Diarrhea and Border Disease

The host range of BVDV-1, BVDV-2, and BDV comprises cattle, sheep, goats, domestic pigs, wild boar as well as many other animal species of the order *Artiodactyla*. BVDV-1 and BVDV-2 mainly infect cattle, while BDV has been detected most frequently in sheep. In some countries infections of sheep and goat with BVDV-1 or BVDV-2 are as frequent as infections with BDV. All these ruminant pestiviruses can cause Border Disease in sheep. Infections of cattle with BDV represent very rare events. Transmission of ruminant pestiviruses, in particular BDV, to pigs can interfere with CSF diagnosis, mainly due to the induction of cross-reacting antibodies.

Bovine viral diarrhea is endemic and widely distributed in all parts of the world. In contrast to CSF, only a few countries in Europe have implemented effective BVD control and eradication programmes resulting in a BVD-free status (Sweden, Norway, Finland, Denmark) or in a significantly reduced prevalence of BVDV in cattle (Switzerland, Germany, parts of Austria and Northern Italy).

As described above for CSFV, ruminant pestiviruses like BVDV-1, BVDV-2 and BDV can be transmitted horizontally and vertically. Horizontal infections can occur via direct and indirect contact. The viruses are excreted via nasal and oral fluids, lacrimal secretions, urine, feces, and semen. The main route of infection is oronasally.

Vertical transmission of BVDV-1, BVDV-2, BDV, and other ruminant pestiviruses from pregnant cattle (days 40–125 of gestation) and sheep (days 16–80 of gestation) to the fetuses can result in a specific acquired immunotolerance against the infecting virus leading to persistent infection of the offspring. These persistently infected (PI) animals are unable to mount an effective humoral and cellular immune response against the persisting virus. PI animals either develop severe disease (see below) or can survive without apparent clinical signs of disease for many years. They shed constantly large amounts of viruses until death and represent the main source of transmission of the virus to susceptible animals within a herd. Accordingly, these PI animals are significantly implicated in the spread of these viruses to other herds, other susceptible hosts, and to other countries.

Clinical Features and Pathogenesis

Classical Swine Fever

Infection with CSFV can result in acute, chronic, and *late onset* forms of CSF, which are characterized by a wide range of clinical symptoms. All forms of CSFV can be observed in both, domestic pigs and wild boar. CSFV infection usually results in fever, thrombocytopenia, leucopenia, and immunosuppression favoring secondary infections. The severity of disease mainly depends on age and immune status of the host animal and virulence of the virus. The disease is more severe and often fatal in young animals, while older breeding animals usually show milder symptoms. Highly, moderately and low virulent viruses can be distinguished. The incubation period of CSF in individual animals is three to ten days. After introduction of low and moderately virulent CSFV in large holdings the disease may remain unrecognized for several weeks. Slow transmission from animal to animal, absence of severe disease and lack of awareness represent significant factors implicated in such high risk periods and can contribute to unrecognized spread of CSF to other farms.

Acute CSF

After infection with moderately and highly virulent CSFV strains piglets and young animals usually develop high fever ($>40^{\circ}\text{C}$) and various clinical signs. In the initial stage of the disease animals may show anorexia, lethargy, conjunctivitis, respiratory and gastrointestinal symptoms. In addition, incoordination of movement, weakness of hind legs, convulsions and other neurological symptoms can be frequently observed. In typical cases of CSF, hemorrhages of the skin complete the clinical picture of the disease. Hemorrhages can be observed during the second week and later stages after infection and most frequently occur on the ears, abdomen, tail, and distal parts of the limbs. In piglets, fatality is usually high and can be up to 100%. In fattening and breeding pigs clinical disease is less severe and less specific. Such older animals can mount an effective immune response resulting in overcoming the virus and recovery from the disease.

Chronic CSF

A minority of infected animals is not able to develop an effective immune response and remain chronically infected. Such chronically infected animals constantly shed infectious virus. While virus-specific antibodies are produced by these animals, they fail to eliminate the virus. The animals show symptoms similar to those observed in acute CSF, but the disease in its initial stage is milder. Later, the disease is characterized by rather unspecific clinical signs including chronic enteritis, wasting, and intermitting fever. Secondary infections with other pathogens frequently occur and can contribute to the clinical signs of the disease. Chronic CSF is always fatal and the animals usually die after two to four months of infection.

Late Onset CSF

As a common feature of pestiviruses, CSFV is able to cross the placenta and infect the fetus. The consequences of diaplacental infections mainly depend on the time of gestation and on viral virulence. Infections during early pregnancy result in abortion, stillbirth, malformations and mummification. Intrauterine infections between days 50–70 of pregnancy with low and moderately virulent CSFV strains which do not kill the pregnant sows can result in the birth of persistently infected offspring and late onset CSF. The persistently infected animals are characterized by an acquired immune tolerance against the infecting virus and shed high

amounts of infectious CSFV for the rest of their life. Animals can appear clinically healthy for longer time periods before they develop a chronic disease condition. Infected animals show poor growth, chronic wasting or occasionally congenital tremor and usually die within the first year of life. Late onset CSF is always fatal. Moreover, it has been reported that early post-natal infections can also result in CSFV persistence.

Bovine Viral Diarrhea and Mucosal Disease

BVDV infection can result in a wide range of clinical consequences. Acute infections of immunocompetent non-pregnant animals usually lead to no or only mild enteric or respiratory disease and frequently remain unnoticed. However, a minority of highly virulent BVDV-1 and BVDV-2 strains can cause a hemorrhagic syndrome with high mortality. BVDV infections of pregnant animals result in transmission to the fetus and a number of severe consequences including embryonic death, abortion, stillbirth as well as malformations and persistent infection of the offspring (see below). Accordingly, the outcome of BVDV infections in cattle is mainly determined by the route of infection (horizontal versus vertical), the immunological status of the host animal, and the virulence of the virus.

Acute BVDV infection

In immunocompetent cattle, acute BVDV infections result in a transient viremia accompanied by fever, transient leukopenia, lymphopenia and immunosuppression. Viremia starts at 3 days after infection and usually lasts up to two weeks until a specific immunity leads to elimination of the virus. In rare cases viremia can last up to three weeks. Clinical presentations of acute BVDV infections can include mild diarrhea or respiratory disease, but in many cases such infections remain unnoticed. BVDV induced immunosuppression decreases the capacity of the immune system to control other viral and bacterial pathogens. Consequently, infections with other infectious agents can result in more severe disease of the respiratory or gastrointestinal tract. In rare cases, highly virulent BVDV strains (mainly BVDV-2) can cause severe thrombocytopenia with hemorrhages and acute fatal disease.

Field BVDV isolates can be categorized into noncp and cp biotypes according to their effects in cell culture. In contrast to cp BVDV, noncp BVDV isolates interfere with the host innate immune response by inhibition of interferon type 1 mediated antiviral defense. Furthermore, it has been reported that cp BVDV strains are faster and more efficiently eliminated by the host compared to noncp BVDV strains. Consequently, cytopathogenicity of BVDV is not associated with increased virulence in acutely infected immunocompetent animals.

Fetal infection with BVDV

Horizontal transmission of BVDV from pregnant cattle to the fetus can result in different severe consequences depending on the age of the fetus at the time point of infection. During the first weeks of pregnancy, prior to the development of cotyledons, BVDV cannot infect the embryo as the virus is not able to penetrate the zona pellucida. After day 30 of gestation infection of the embryo can result in embryonic death which may represent an important cause for reduced conception rates of dams. Fetal death is most frequently observed after infection of the dam during early gestation, but can occur at all stages of gestation. Another important consequence after infection of the fetus with noncp BVDV between 40 and 125 days of gestation is the establishment of persistent infection of the fetus resulting in the birth of persistently infected (PI) calves. After infection of the dam between 80 and 180 days of gestation, the virus is transmitted to the fetus during the period of organogenesis and can cause cerebellar hypoplasia, ocular degeneration, brachygnathism, and skeletal malformations. After infection during the last trimester of gestation the fetus can mount an effective immune response including neutralizing antibodies capable of elimination of the virus. Such infections usually do not cause disease and the respective animals are apparently healthy at birth.

Persistent BVDV infection

Infection of the fetus with noncp BVDV at a stage prior to immunocompetence of the fetus can result in a highly specific immunotolerance against the infecting virus and the birth of PI calves. As a consequence, persistently infected animals are not able to produce virus-specific antibodies and to eliminate the virus. The ability of noncp BVDV to inhibit the induction of type 1 interferon in the fetus is a crucial prerequisite for the establishment of lifelong persistent infection. PI animals are efficient virus producers, shed large amounts of viruses in all secretions and excretions and thus are significantly implicated in the spread of BVDV. PI animals can either appear clinically healthy or more frequently present as weak calves with various clinical signs due to increased susceptibility to secondary infections with other infectious agents. Another consequence is the onset of mucosal disease.

Mucosal disease

Only persistently infected animals may develop mucosal disease. Affected animals show acute severe diarrhea, dehydration, as well as erosion and ulceration of the mucosa of the oral cavity, esophagus, and gastrointestinal tract. Mucosal disease frequently occurs within the first two years of life and is always fatal. Affected animals die within a few days or a few weeks after onset of disease. In mucosal disease affected animals, a cp BVDV variant is always present in addition to the persisting noncp BVDV. Accordingly, the emergence of cp BVDV in animals persistently infected with noncp BVDV is crucially implicated in the pathogenesis of mucosal disease. In most cases the cp viruses emerge in the PI animal by RNA recombination including deletions and duplications of viral sequences as well as insertions of cellular RNA sequences. In rare cases point mutations in the NS2 protein coding region can result

in the emergence of cp BVDV. Alternatively, superinfection with an antigenically highly similar cp BVDV strain can directly cause mucosal disease within a few weeks after superinfection. A so called late onset mucosal disease results from RNA recombination between a superinfecting antigenically less similar cp BVDV strain with the persisting noncp BVDV strain and usually occurs about 3–4 months after infection with a cp BVDV field strain or after vaccination with a live attenuated cp BVDV vaccine.

Border Disease

Border disease (BD), also known as *hairy shaker disease*, was first described in the late 1950s. Again, intrauterine infections of pregnant sheep and goat are by far more important than acute infections of immunocompetent animals. Intrauterine infection during early pregnancy can cause fetal death, mummification, abortion, and stillbirth. Intrauterine infections during the 17th and 80th day of gestation can result in the birth of lambs with tremor, ataxia, brain malformations, hairy fleece, and poor growth. Alternatively, apparently healthy lambs can be born. Both clinically affected and apparently healthy lambs can be persistently infected. As described above for CSF and BVD, persistently infected animals constantly shed large amounts of infectious virus and therefore play an important role in virus transmission. In rare cases, PI lambs which recovered from disease can develop a syndrome similar to mucosal disease. Infections of immunocompetent sheep and goat mostly lead to either no or mild transient clinical signs.

Prevention and Control

In order to prevent economic losses caused by pestiviral infections and to prevent spread of the disease in domestic or wild animals control measures are often applied. Vaccination, eradication or a combination of both are common methods. There are several ways to prevent pestiviral infections and different strategies have been developed. Reliable laboratory diagnostic tests and efficacious vaccines are prerequisites of efficient preventive control measures.

Diagnosis

Acute infection with pestiviruses results in transient viremia. Since these viruses grow readily in cell cultures of their species of origin, classical diagnostic methods were based on the isolation of viruses from blood or organs of infected animals. Isolated cp BVDV can be detected using plaque assays, while noncp viruses can be visualized either by immunofluorescence or enzyme immuno techniques.

Since tissue culture is time consuming and expensive, rapid screening tests have been developed. Immunohistochemistry using mono- or polyclonal antibodies can be applied in post-mortem samples of infected animals.

Antigen-capture enzyme-linked immunosorbent assays (AgC-ELISA) are being used to diagnose cattle persistently-infected with BVDV. Since monoclonal antibodies are used in these test systems they are highly specific. Either blood or ear-notch samples are suitable for these tests. The most common method for the rapid diagnosis for ruminant and porcine pestiviruses is RT-PCR, which is applied using either individual or pooled samples of blood, milk, other body fluids, ear notches of cattle or organ suspensions.

In order to achieve a more precise characterization, viruses are often sequenced. Either parts or the whole genome are used, respectively. By comparing the sequence data with published sequences in data bases the information can be used to obtain detailed taxonomic or epidemiological insights.

As the result of acute infection or vaccination animals seroconvert. Classical methods for detecting virus-specific antibodies are virus neutralisation assays. These assays are highly specific and sensitive and they allow serological differentiation of viral strains. However, since they are based on the use of cell culture, they are expensive, time consuming and labor-intensive. Today these assays are still used for reference purposes. For the rapid and large scale screening of samples a number of alternative tests, in particular ELISAs for the detection of antibodies against structural and/or non-structural viral proteins are being used. Variants of these tests are direct, indirect or competition or double antigen ELISAs. Recombinant viral proteins and monoclonal antibodies have been used to improve sensitivity and specificity of these assays. All these tests have in common that they are relatively inexpensive and they are suitable for mass screening because they can be automated. Antibody detection can be performed in individual or pooled serum samples as well as in bulk milk samples of ruminants. Despite good characteristics of these ELISAs with respect to sensitivity and specificity, positive results are sometimes required to be confirmed by virus neutralization test.

Vaccines

Vaccines have been used as one of the most important control tools against pestiviral infections. Today there are a number of vaccines available, in particular against BVD and CSF.

Vaccines against classical swine fever

Currently modified live vaccines (MLV) are the vaccines of choice for the prevention of CSF. Conventional MLVs, e.g., the lapinised C-(China) strain of CSFV, are safe, highly efficacious and relatively inexpensive. However, when using these vaccines a serological distinction between vaccinated and infected animals is not possible. This might impede an organized effort for the control of the infection. Therefore, numerous efforts were made to develop DIVA (Differentiating Infected from Vaccinated Animals) vaccines, which would allow the distinction of naturally infected and vaccinated pigs. First DIVA vaccines were based on the immunogenic

E2 envelope protein of the virus, which had been expressed in baculoviruses. These vaccines were on the market for a few years, however, they have been abandoned because their efficacy was inferior to MLV. Nevertheless, at least one E2 subunit vaccine has recently been licensed in China. Moreover, considerable efforts have been undertaken to develop live DIVA vaccines. Current live DIVA vaccines have been developed using recombinant techniques, e.g., by constructing a chimeric virus using a BVDV backbone and the immunogenic E2 envelope protein of CSFV. Other vaccines are based on the use of adenovirus vectors. In parallel serological tests were developed to discriminate infected from vaccinated animals.

Vaccines against bovine viral diarrhea

First MLVs against BVD were already developed in the 1960ties. They were highly efficacious, however, they could not be used in pregnant cattle, because transplacental transmission of vaccine virus often produced damage comparable to natural infection with BVDV. In response to these safety issues killed vaccines were developed, which in general had a very good safety record and animals of all ages could be vaccinated including pregnant animals. However, killed vaccines had to be administered repeatedly and the immune response was inferior to that of MLVs. In consequence fetal protection of pregnant animals was often insufficient. BVDV infection of vaccinated pregnant cattle often interfered with pregnancy and the whole spectrum of BVDV-related malformations was observed including the birth of PI calves. A rare phenomenon associated with one particular inactivated vaccine was observed in 2007 and subsequent years in Europe. A new disease “bovine neonatal pancytopenia (BNP)” leading to the death of newborn calves emerged. Epidemiological studies indicated a connection between this new syndrome and vaccination with an inactivated vaccine against BVD. In serum and colostrum of dams which had given birth to calves with BNP, alloantibodies reacting with blood leukocytes of calves were detected. Apparently impurities derived from bovine cells or fetal calf serum that was used for the production of the vaccine virus were presented by a powerful adjuvant in the vaccine thereby eliciting the production of alloantibodies. The vaccine was withdrawn from the European market. Today about 20 predominantly killed vaccines are licensed in the EU. All but one product are directed against BVDV-1 only. In North America close to 200 BVD vaccines, killed and live and sometimes in combination with other antigens, are on the market. Some of the vaccines are directed against BVDV-1 and BVDV-2. Since a few years, a novel MLV is on the market that is based on a combination of deletion mutants of noncp BVDV-1 and BVDV-2 both lacking N^{pro} and the ribonuclease activity of E^{ms}. This MLV is safe to administer to all age classes of cattle including pregnant animals and has been shown not to establish an infection in foetuses.

The main purpose of vaccination against BVD is to achieve a strong fetal protection in order to prevent the production of new PI animals. Vaccines with this potency are well suited to also prevent all other consequences of acute BVDV infection, i.e. transient immunosuppression and subsequent clinical or subclinical symptoms.

Control of Classical Swine Fever in Domestic Pigs

CSFV is arguably the most important pathogen of pigs. As mentioned above, domestic and feral pigs, as well as wild boar are equally susceptible. Suitable methods for the control of CSF in domestic pigs are stamping out of the infection, i.e., killing and destruction of infected and suspected contact animals in combination with movement restrictions and other strict biosecurity measures. A ban of swill feeding is a mandatory and very effective prophylactic control measure. Usually farmers are compensated for their losses. Stamping out is generally used in countries that are free from CSF and where vaccination is prohibited.

Prophylactic vaccination can also be used as a control tool. It is applied, when new outbreaks can no longer be controlled by stamping out alone. In countries with endemic CSF vaccination is used in order to reduce economic losses. When used systematically, i.e., when the vast majority of a pig population is covered, the number of susceptible animals will decrease to an extent that the spread of the infection is no longer supported. The basic reproductive number of infection (R_0) drops below 1. One infected animal infects less than one susceptible animal. As a result the infection fades out and CSF will eventually be eradicated. This strategy has been used successfully in domestic pigs in the 1970ties in some regions of The Netherlands and from 2007 to 2010 in the Romanian backyard pig population.

Control of Classical Swine Fever in Wild Boar

CSFV can also infect wild boar. The epidemiology of the infection depends on a number of factors, in particular virulence of the virus and density of the animal population. From early experience it was thought that CSF outbreaks in wild boar are self-limiting. However, more recent outbreaks, e.g., in the 1990s in Germany became endemic. Possible reasons were high population densities and moderate virulence of the virus. CSF in wild boar is a severe threat to domestic pig holdings in the affected area. Therefore effective control measures are crucial.

Key parameters for the successful control of CSF in wild boar are the number of susceptible animals, R_0 (basic reproduction number of infection) and viral virulence. Fresh outbreaks result in a large number of deaths in younger age classes, while most older animals survive and will become seropositive. The latter are immune for the rest of their lives. This scenario may lead in low density populations to a drop of the basic reproduction number below the critical threshold ($R_0 < 1$), and outbreaks are self-limiting. In contrast, when population density is high there will always be enough susceptible animals due to intense reproduction to maintain the infection ($R_0 > 1$). CSF may become endemic for many years. Viral virulence influences these situations by the proportion of killed vs. surviving animals.

The prime purpose of any control measure is the reduction of susceptible animals to a threshold that R_0 drops below one. In sparsely populated areas this might be the case after the initial phase of the outbreak when a part of the population has succumbed to the infection and the remaining animals are immune. In these situations hunting is often banned in order not to disturb the population and keep the infection in the affected area. Natural boundaries, e.g., major rivers or mountains are helpful in containing the infection. In dense populations the number of susceptible animals has to be reduced by external intervention:

- Hunting activities should focus on the young age classes of wild boar, since older animals in an infected area are most likely to be immune. However, due to the high reproduction rate of wild boar experience has shown that hunting alone as a control tool is insufficient and does not result in eradication of the infection.
- Trapping might be considered a variant of hunting. Positive experiences using this control tool have been made, e.g., in Bulgaria. This strategy does not disturb the population and larger numbers of susceptible animals can be removed from the population.
- Oral immunization with baits containing MLV has been shown to be highly effective, and when applied over a period of a few years may significantly contribute to the extinction of the infection in endemic areas. A proven strategy is to vaccinate twice per year, i.e., in spring and autumn. Each vaccination is repeated once after four weeks. Baits are distributed in small restricted areas. Although very young age classes are not well reached by oral immunization, this strategy can reduce the number of susceptible animals sufficiently to reach $R_0 < 1$.

Sometimes a combination of the above strategies leads to success.

Control of Bovine Virus Diarrhea

Systematic control of BVD including the removal of PI animals was long discussed controversially, because of the ubiquitous occurrence of the infection and the stealthy nature of the infection. In addition the economic impact of BVD was underestimated for a long time. Today the economic dimension of BVD is fully appreciated. Transient immunosuppression and fetal infections produce disease and economic losses can be dramatic. Meanwhile BVD is considered to be the most important viral disease of cattle. The infection is spread by direct contact of acutely infected animals and by fomites. However, the most important source of BVDV spread are persistently infected (PI) cattle. They are the virus reservoir in cattle populations and consequently they play a pivotal role in any control programme. The life span of PI animals ranges from a few hours after birth up to seven or eight years. During their lifetime they shed large amounts of virus at any time. This is unique and the number of new infections transmitted by PI cattle may be unlimited, depending on frequency of animal contacts.

For more than fifty years vaccines have been used to prevent clinical BVD. Once the economic consequences of intrauterine infection were recognized, an additional requirement for licensing of vaccines was reliable fetal protection. However, despite widespread use of vaccination BVD prevalence did not change over the decades. The main reason for this failure was due to the remaining of PI animals as a powerful reservoir in cattle populations. Poor efficacy of some vaccines might have been an additional factor. In contrast to many other animal infections, e.g., CSF or rinderpest, BVD will never be eradicated using vaccination alone.

With the advent of inexpensive laboratory screening methods, it was possible to identify and remove PI cattle. Scandinavian countries were the first in the early 1990s to implement systematic control programmes by searching with serological methods for herds with active BVD infections. PI animals were identified in seropositive herds and removed. After their removal herds were monitored in regular intervals and, when seronegative, they were declared BVD-free. Strict biosecurity measures and movement restrictions for non-negative cattle were accompanying measures of these compulsory programmes. A few years of systematic control resulted in a BVD-free status of the Scandinavian countries. Vaccination was banned throughout the programme. Economic analyses showed that the cost benefit ratio of BVD control was highly positive. Austria followed a few years later with a similar control programme. In 2008 Switzerland chose a slightly different approach: The whole national cattle population was tested for PI animals. Thereafter all newborn calves were tested for BVD. The final phase of the programme is the constant serological surveillance of the cattle population. Within 3 years PI prevalence was reduced from 1.3% to 0.02%. Germany started a systematic effort to reduce PI prevalence in 2011 by testing newborn calves for BVDV. Vaccination as an additional control tool was allowed. PI prevalence was reduced from 0.48% (2011) to 0.01% (2017). Similar control programmes were initiated in Belgium, Scotland and Ireland.

In countries or regions without a compulsory programme for systematic BVD control it is possible to prevent economic damage on a herd basis by removing PI animals, regular vaccination in order to prevent reinfection with BVDV and strict biosecurity.

Control of Border Disease of Sheep

There are a few vaccines against BD available. Since the epidemiology of BD is very similar to BVD analogous strategies for its control can be used.

Capripoxviruses, Parapoxviruses, and Other Poxviruses of Ruminants (*Poxviridae*)

Philippa M Beard, The Pirbright Institute, Pirbright, United Kingdom and The Roslin Institute, University of Edinburgh, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Introduction

Poxviruses cause disease in farmed and free-living ruminants, ranging from mild, self-limiting lesions to systemic, fatal disease. The species of ruminant poxvirus covered in this article are listed in [Table 1](#). The most common is Orf virus (ORFV) which is found worldwide and causes mild, transient, proliferative lesions on young sheep and goats. In contrast, the most severe poxvirus diseases of ruminants are caused by Sheeppox virus (SPPV), Goatpox virus (GTPV) and Lumpy skin disease virus (LSDV). These three viruses are recognised as causing high consequence transboundary diseases with a substantial morbidity and mortality burden.

Classification

The family Poxviridae contains two subfamilies – Entomopoxvirinae and Chordopoxvirinae. Poxviruses that affect ruminants are found within the Chordopoxvirinae subfamily and include species within the genera Capripoxvirus, Orthopoxvirus and Parapoxvirus.

Virion Structure

Poxviruses have a complex virion structure. The viral genome and transcription factors are believed to be contained in a folded tubular “nucleocapsid” structure. This is contained within the very recognisable biconcave core structure which has a lateral body in each concavity. The core structure is then enclosed within one to three lipid membranes.

Orthopoxviruses produce four virion types that are distinguished by the number of membranes surrounding the core and their cellular location – the intracellular mature virion (IMV), the intracellular enveloped virion (IEV), the cell-associated enveloped virion (CEV) and extracellular enveloped virion (EEV). In some recent papers IMVs are referred to as mature virions, IEVs as wrapped virions, and EEVs as extracellular virions.

Electron microscopy studies have shown parapoxviruses (PPV) produce IMVs, IEVs, CEVs and EEVs analogous to orthopoxviruses. These studies have also revealed a unique feature of the PPV virion – a raised surface tubule protein that is wrapped around the virion core to produce a “ball of wool” effect. This protein is encoded by the ORF104 gene; mutated viruses with this ORF disrupted produced morphologically aberrant particles and failed to create EEVs.

Very little work has been reported on the virion structure of capripoxviruses (CPPV). Examination of LSDV, SPPV and GTPV purified virions using electron microscopy have identified CPPV virion size as length 293–299 nm and width 262–273 nm, consistent with other poxviruses, and the absence of any surface tubular proteins. Electron microscopy images from LSDV-infected tissue have revealed IMV and IEV-like structures ([Fig. 1](#)).

Genome

The CPPV genome structure is similar to other poxviruses. It consists of a double stranded linear DNA genome that is 25% GC-rich, approximately 150 kbp in length, and encodes around 156 ORFs. Each end of the linear genome encodes for a

2200–2300 bp inverted terminal repeat sequence, and the linear ends of the genome are joined with a hairpin loop. The central region of the CPPV genome contains ORFs predicted to encode proteins required for virus replication and morphogenesis and exhibit a high degree of similarity with genomes of other mammalian poxviruses. In the outer regions of the CPPV genomes this similarity is lower. These ORFs contain genes encoding proteins likely to be involved in viral virulence and host range determinants. The CPPV isolates sequenced to date are genetically very similar, exhibiting 96% nucleotide identity. However phylogenetic analysis groups the isolates into the three species – SPPV, GTPV and LSDV.

The genome of the PPVs is one of the smallest amongst the poxviruses at 134–139 kbp. It is also unusual in its high GC content, around 64%. The only other poxvirus with a similarly high GC content is the human pathogen molluscum contagiosum virus. The PPV genome encodes 130–132 ORFs and exhibits the standard poxvirus genome structure with inverted terminal repeats and hairpin loops. Genes encoding essential functions are found centrally and ORFs encoding proteins involved in virus pathogenesis towards the periphery. PPV species exhibit greater genetic variation than CPPV, for example the amino acid identity of PCPV compared to BPSV is only 72%.

Life Cycle

It is widely presumed that the cellular life cycle of CPPV and PPV mirrors that of the well-studied orthopoxvirus genus. This is supported by microscopic and ultrastructural findings indicating cellular entry is followed by formation of cytoplasmic viral factories, and morphogenesis from immature virions to IMV, IEV, and CEV followed by virion release.

Sheeppox and Goatpox Virus

Epidemiology

Sheeppox and goatpox occur in Africa, the Middle East, and Asia including India and China. There are regular outbreaks on the periphery of these endemic zones, as for example Vietnam (2005 and 2008), Taiwan (2010), and Greece (2018). Participatory studies using farmer interviews have indicated these diseases are widespread in low and middle income countries. For example, 80% of farmers in Sudan had experienced an outbreak of sheeppox at some time in the past, while 14% of sheep farmers in Algeria reported current cases of sheeppox in their flock. Serological studies to estimate the prevalence of SPPV and GTPV are few but support the theory that the diseases are widespread. 17% of sheep and 14% of goats tested in west Amhara region of Ethiopia were seropositive, while 17% of goats were seropositive in the Layyah Punjab region of Pakistan. Morbidity, mortality and case fatality rates (CFR) of sheeppox and goatpox vary between outbreaks. In an epidemic of sheeppox in Israel morbidity was 20.5% and CFR 19.3%. In an epidemic of sheeppox in Mongolia morbidity was 14.5% and CFR 6%. In imported, unvaccinated sheep in a feedlot

in Jordan an outbreak of sheeppox caused 21.5% morbidity and CFR 41%. In more endemic settings in Sudan morbidity due to sheeppox varied between flocks from 0.45%–15.9% and CFR 0%–33%.

SPPV and GTPV are widely accepted to cause substantial economic hardship with particularly severe impacts on subsistence livestock owners in low and middle income countries. However the economic impact of SPPV and GTPV is poorly studied. A study from 2000 in India estimated it would take 6 years for a farm to recover from an outbreak of SPPV or GTPV, with average annual losses in income of 30%–43%, depending on flock type and the owner's actions.

SPPV and GTPV spread from animal to animal via direct contact or insect vectors such as biting flies (*Stomoxys calcitrans*). Aerosol infection of sheep has been achieved experimentally by spraying SPPV or GTPV into the close environment or directly into the face of sheep, although this method of transmission was found to be less effective than prolonged direct contact with a diseased animal. Under experimental conditions, 100% of animals inoculated intradermally with a virulent strain develop disease.

The host tropism of SPPV and GTPV strains varies. Some SPPV and GTPV viruses are highly host specific and cause disease in the field only in sheep or goats respectively. Other strains cause disease in both sheep and goats. The host specificity of SPPV and GTPV has been tested experimentally. Two GTPV strains, one from Vietnam and one from Yemen, were inoculated into both goats and sheep. Both isolates caused more severe disease in goats, the Yemen isolate was also moderately pathogenic in sheep. However the Vietnam isolate caused only very mild disease in sheep. This supports evidence from the field that different SPPV and GTPV strains exhibit variable host preference. The genetic determinants of SPPV and GTPV strain virulence and host preference are unknown.

Clinical features and pathology

Experimentally the incubation period of sheeppox and goatpox is 4–6 days following intradermal or subcutaneous inoculation. Both diseases are characterised by the appearance of round to oval, slightly raised, well demarcated lesions up to 2 cm in diameter on the skin. The appearance of skin lesions coincides with other clinical signs including severe pyrexia, purulent ocular and nasal discharge, anorexia, dyspnoea, lethargy, diarrhoea and superficial lymphadenopathy. The cutaneous lesions of sheeppox and goatpox are similar to the classic orthopoxvirus “pocks” and develop from macule to papule to pustule and then scab. Ulceration of the cutaneous lesions is a feature of some outbreaks. Lesions are often more numerous on sparsely haired areas of the body. Post mortem examination of cases of sheeppox and goatpox may reveal lesions in internal organs, described as firm red to white nodules in the lungs and intestines, liver and kidneys.

Sheeppox and goatpox can occur in the field as a mixed infection concurrent with bluetongue virus, peste-des-petits-ruminants virus, orf virus or *Mycoplasma capricolum* subsp. *capripneumoniae*. These mixed infections often result in mortality over 50%.

Histopathology

The dominant histopathological features seen in sheep and goats infected with SPPV and GTPV are keratinocyte hyperplasia and necrosis accompanied by vesicle formation in the epidermis, with large basophilic intracytoplasmic inclusion bodies often present in the degenerate and necrotic keratinocytes and in the epithelium of adnexal structures. Within the dermis oedema and haemorrhage is accompanied by infiltrating large histiocytic cells with a vacuolated nucleus and marginated chromatin. These cells are often found in perivascular areas, and can contain prominent large basophilic intracytoplasmic inclusion bodies. A necrotising vasculitis with histiocytic cells infiltrating the walls of blood vessels has been reported within the dermis and subcutis. In the lungs, a severe necrotising bronchiointerstitial pneumonia is present, with large histiocytes and other mononuclear cells infiltrating the interstitial tissues, particularly in peribronchiolar and perivascular areas. Large histiocytic cells accompanied by necrosis and vasculitis have also been noted in the liver, kidney, lymph nodes and gastrointestinal tract. Immunolabeling of tissues from affected animals have identified CPPV antigen in histiocytic cells, keratinocytes, and bronchiolar epithelial cells.

Pathogenesis

Most of the work on sheeppox and goatpox pathogenesis comes from time course studies following experimental infection. After intradermal or subcutaneous inoculation, virus disseminates from the inoculation site to distant cutaneous sites and other organs, possibly via a monocyte/macrophage associated viraemia. Virus is detected in the skin distant from the inoculation site 3–4 days later, and virus load increases up to day 7 or 8 and remains high until day 14 when it begins to gradually decrease. The skin and lung appear to be the major target organs for these viruses.

Diagnosis

SPPV and GTPV are often strongly suspected based on the clinical signs displayed by the affected animals. Differential diagnoses include orf, dermatophilosis, dermatophytosis, bacterial pyoderma, and mange. Confirmation of the diagnosis of sheeppox or goatpox is usually made on the basis of detection of SPPV or GTPV DNA within lesions or blood. A PCR based on the CPPV-encoded G-protein-coupled chemokine receptor (GPCR) gene can be used to differentiate between the three CPPV species. A CPPV neutralisation test can be used to detect neutralising antibodies in immune animals. Histopathology and electron microscopy are occasionally used for confirmation of the disease but are time consuming and expensive.

Treatment

Due to their high consequence outbreaks of SP and GP are often treated by euthanasia of affected and in-contact animals ("stamping out"). In circumstances where treatment is appropriate and economically viable sheeppox and goatpox may be treated with supportive therapy and antibiotic coverage to reduce secondary bacterial infections.

Prevention

Live attenuated strains of CPPV are widely used as vaccines to prevent sheeppox and goatpox. Similar to orthopoxviruses CPPVs are cross-protective within genus therefore one CPPV live attenuated vaccine can be used to protect against all three CPPV species.

Lumpy Skin Disease Virus

Epidemiology

Lumpy skin disease affects cattle and water buffalo and occurs in Africa, the Middle East, southeast Europe, the Caucasus, Russia and Kazakhstan. LSD was first described in southern Africa in the 1920s, from where it gradually spread northwards throughout Africa and entered the Middle East in the 1980s. Outbreaks occurred sporadically in this region until 2012 when the virus began to spread rapidly over long distances into new areas including Iran, Iraq, Jordan, Turkey, Russia and, in 2015, into mainland Europe (Greece). The disease has since been reported in many Balkan and Caucasian countries. The reasons behind the rapid and sudden spread of LSDV through the Middle East, Europe and western Asia since 2012 are unclear. Hypotheses include climatic conditions conducive to LSDV spread, or civil conflict hampering veterinary services and disrupting livestock movement patterns.

LSD is highly host specific with extensive serological surveys of wildlife in southern Africa finding no evidence for LSDV infection of any species other than cattle and water buffalo.

The mode of transmission of LSDV differs from SPPV and GTPV. Experimental studies found no evidence for direct transmission of the virus between animals, instead transmission is strongly believed to be via arthropod vectors. It is unclear if this vector borne transmission is biological or mechanical. LSD has been successfully transmitted experimentally via *Aedes aegypti* mosquitoes. LSDV was retained by the *Ae. aegypti* mosquitoes and transmitted to recipient cattle up to 6d after feeding on donor cattle. This work represents the only unequivocal demonstration of experimental transmission of LSD via vectors. In contrast two other species of mosquito (*Culex quinquefasciatus* and *Anopheles stephensi*) retained LSDV for only 24 h and did not transmit LSDV to recipients. Similarly, LSDV was detected in *Stomoxys calcitrans* (biting flies) and midges (*Culicoides nubeculosus*) after feeding the insects on a LSD-affected animal but transmission of the virus or disease to a naïve recipient animal was unsuccessful. Experimental transmission of LSDV has been demonstrated by transferring a *Rhipicephalus appendiculatus* ticks from donor to recipient animals mid-feed although the latter did not show clinical disease.

LSDV has shown a propensity for the male reproductive tract, with virus isolated from necrotic lesions in the testes and epididymis, and from the semen of LSD-affected bulls. Clinical LSD accompanied by a severe necrohaemorrhagic vulvovaginitis and metritis was demonstrated in a group of heifers artificially inseminated with semen spiked with virulent LSDV, suggesting this could be a route of LSD transmission.

A number of detailed epidemiological studies on LSD have been published. Communal grazing, proximity to water sources, temperature and rainfall have all been associated with outbreaks of LSD and are consistent with vector-borne transmission of virus. A well-documented LSD outbreak in a large dairy herd in Israel in 2006 was analysed and transmission by indirect or direct contact modelled. Indirect transmission was the only parameter that could explain the outbreak dynamics with an overall effect over 5 times larger than direct contact. Outbreaks in south-east Europe were strongly seasonal, occurring in spring and summer with very few, if any, outbreaks over winter. The median LSD spread rate in these outbreaks was calculated to be 7.3 km/week, consistent with vector-borne spread.

Morbidity and mortality in LSD outbreaks are lower than sheeppox and goatpox. Recent reports from epidemic areas in the Middle East and Europe have indicated morbidity of 9%–26%, and mortality from 0.5% to 2%. In comparison, data from 1161 LSD outbreaks over 15 years in an endemic area in Uganda reported a lower disease impact with morbidity 4.77% and mortality 0.03%.

Clinical features

LSD has an incubation period of approximately 7 days after experimental inoculation. The first sign of disease is pyrexia, followed by the appearance of distinctive and numerous raised cutaneous lesions from 0.5 to 5 cm in diameter which develop over 3–4 days from macule to papule to nodule. The cutaneous lesions are often accompanied by oral, nasal and ocular discharge, lethargy, anorexia, and in lactating animals a rapid drop in milk production. Brisket oedema and superficial lymphadenopathy are also reported. After 1–2 weeks the skin nodules become necrotic and the centre eventually sloughs, leaving a defect in the skin which can predispose the animal to secondary bacterial infection or myiasis.

Pathology

Gross pathology of LSD is characterised by multifocal, acute to chronic nodular dermatitis, with necrosis and ulceration. Histologically there is mild acanthosis, ballooning degeneration of keratinocytes with intracytoplasmic intracellular inclusion bodies, histiocytic inflammation of the dermis and fibrinonecrotic vasculitis (Fig. 2).

Fig. 2 Microscopic image of the histopathological changes in the epidermis of a nodule from a calf experimentally inoculated with LSDV. The tissue was fixed in buffered formal saline, processed to a wax block, and stained with haematoxylin and eosin using routine methods. The arrows point to eosinophilic intracytoplasmic inclusion bodies present in the keratinocytes.

Pathogenesis

Few details of the pathogenesis of LSD have been determined, and our understanding of how the virus causes disease is extrapolated from the more meticulously studied poxviruses such as the orthopoxviruses. It is believed that arthropod vectors inoculate LSDV into the skin of the animal, the virus then circulates in the blood stream via a low level viraemia and disseminates into distant cutaneous sites as well as the reproductive tract and other internal organs. Experimental models of LSD have consistently found that only around 50% of cattle inoculated with LSDV develop clinical disease; the host factors which control this variable susceptibility are unclear.

Diagnosis

LSDV is often strongly suspected based on the characteristic clinical signs. PCR is used to detect viral DNA in fluids or tissues to confirm disease. Virus isolation and electron microscopy can be used for diagnosis but are relatively expensive and time-consuming techniques. A virus neutralisation test can be used to detect neutralising antibodies in immune cattle. ELISA-based serological tests to detect antibodies to LSDV have proved challenging to develop due to the complex and variable antibody response to poxvirus infection. Differential diagnoses for LSDV are bovine herpesvirus 2 infection (sometimes known as pseudolumpy skin disease), dermatophilosis, demodicosis, besnoitiosis, Hypoderma bovis infection, and cutaneous tuberculosis.

Treatment

In epidemic situations treatment of LSD is rarely attempted, with stamping out of affected and in-contact cattle often mandated. In circumstances where treatment is appropriate and economically viable LSD may be treated with supportive therapy and antibiotic coverage to reduce secondary bacterial infections of the skin lesions.

Prevention

LSD can be prevented by vaccination with a live-attenuated CPPV strain. The most commonly used vaccine for LSD is the "Neethling" attenuated LSDV strain. Vaccination can be accompanied by movement restrictions to prevent the spread of the disease. Detailed analyses of the recent outbreaks in Europe and neighbouring countries have found vaccination to be a highly effective method of disease prevention, while questioning the effectiveness of a comprehensive stamping out policy.

Orf Virus

Epidemiology

Orf, also known as scabby mouth or contagious ecthyma, is caused by infection with orf virus (ORFV) and found worldwide wherever small ruminants are reared. The disease can be readily recognised from its characteristic scabby lesions around the mouth and nares of lambs and kids. The morbidity can be high but mortality is rare, and the disease is usually self-limiting. ORFV is very robust and can survive months in dry conditions, likely promoting recurrence of the disease in the spring lambing season. Like many other PPVs, ORFV is zoonotic with regular reports of transmission of the virus to people where it causes a focal proliferative dermatitis. Cases in humans have been associated with high risk professions such as veterinarians and farm workers, and with cultural celebrations which involve animal slaughter.

Molecular epidemiological studies of PPVs have been carried out, often targeting ORF011 (the B2L gene), which is the PPV orthologue of the vaccinia virus (VACV) Copenhagen strain gene F13L. A recent comprehensive study compared 23 isolates using ORF011 and ORF032 to enable categorisation of the PPV isolates to the correct genus.

Clinical features and gross pathology

Orf is characterised by proliferative, focal to regionally extensive scabby lesions most commonly around the mouth of lambs and kids. The lesions develop from an initial erythema, to macules, papules, vesicles, pustules and proliferative scabs. The disease has no systemic phase and is usually self-limiting however it can cause reduced growth rates in affected animals, most likely by inhibiting feeding and/or suckling. Less commonly the infection can spread to the udder of the ewe or doe, causing a dermatitis of the teat. There are occasional reports of ORFV causing more severe outbreaks of disease.

Reinfection can occur but the disease is milder and resolves more rapidly.

Histopathology

The histopathology of orf is focal to regionally extensive moderate to marked proliferative dermatitis or cheilitis, with marked dermal vascular proliferation and dilation. Early lesions are characterised by severe acanthosis and ballooning degeneration of keratinocytes, with elongated rete pegs often a key feature. Dermal changes include a moderate inflammatory cell infiltrate (mainly lymphocytes and histiocytes) with oedema occasionally causing subepidermal vesicles.

Pathogenesis

Orf virus (ORFV) infects broken or scarified skin and is therefore more often reported in animals grazing thistle, gorse or stubble. The virus initially replicates in regenerating keratinocytes immediately below the stratum corneum, before spreading laterally into adjacent epithelium. The inflammatory response consists of neutrophils, basophils and mast cells followed by abundant MHC class II+ histiocytic cells, T and B lymphocytes.

A number of virulence factors encoded by ORFV have been studied and their mechanism of function elucidated. These include GIF and VEGF-E.

GM-CSF and IL-2 inhibitory factor (GIF) is encoded by ORF117 of ORFV. This protein appears to be unique to PPVs with no orthologue found in any other Chordopoxvirus species. GIF is expressed as an immediate-late protein and binds sheep, but not human, GM-CSF and IL-2 and antagonises the bioactivity of both. More specifically GIF interferes with the myeloproliferative and chemoattractant properties of GM-CSF and the activation of lymphocytes and NK cells by IL-2. Recently, a structural biology approach was taken to identify how GIF targets these two different chemokines. This work revealed that GIF forms a dimer and binds two molecules of the target cytokine. GIF achieves this without sharing any structural similarity with either cognate cytokine receptor. GIF binds both GM-CSF and IL-2 with high affinity, but uses mutually exclusive interaction sites for each cytokine. GIF is the only such dual-purpose viral decoy receptor characterised to date.

Orf virus encodes a fifth member of the vascular endothelial growth factor family, known as VEGF-E. This protein binds to VEGF-receptor 2 (VEGFR2) and neuropilin-1, but not VEGFR1 or VEGFR3. VEGF-E exhibits biological activity consistent with its receptor binding, causing increased mitogenic activity of endothelial cells and increase vascular permeability. An ORFV strain lacking VEGF-E has been constructed and characterised *in vivo*. This mutated strain exhibited reduced gross pathology with particularly striking loss of the characteristic erythema seen in early orf lesions. Histologically the strain lacking VEGF-E produced less inflammatory cell influx, reduced hyperplasia of the epithelium, smaller pustules which resolved more rapidly, and reduced neovascularisation in the dermis. VEGF-E is therefore a key factor driving the pathological changes associated with ORFV infection, with a strong angiogenic role contributing to the characteristic neovascularisation and capillary dilation. The biological activities of VEGF-E have been used in a mouse model to promote wound healing. Expression of recombinant VEGF-E in normal skin caused epidermal thickening and increased numbers of endothelial cells and blood vessels in the dermis. In wounded skin, VEGF-E enhanced wound re-epithelialisation and increased thickness of neovascularisation, suggesting a therapeutic application for VEGF-E in promotion of wound healing.

Diagnosis

Clinical signs are often used to diagnose orf. Polymerase chain reaction (PCR) can be used for confirmation if needed. The main differential diagnoses for orf are sheeppox, goatpox, foot and mouth disease, bluetongue, peste-des-petits-ruminants, and mange.

Treatment

Most cases of orf are self-limiting, however support therapy is indicated when the clinical signs are more severe.

Prevention

Vaccination with a live attenuated strain of ORFV is the recommended method for reducing the disease. Vaccination is required on an annual basis.

Bovine Papular Stomatitis Virus

Bovine papular stomatitis virus (BPSV) causes mild disease in calves, characterised by flat to slightly raised red to brown macules and papules, sometimes progressing to ulcers, in the mucus membranes of the oral cavity. Diagnosis, treatment and prevention measures are rarely required, as severe disease is very rare. In common with other PPVs, BPSV is zoonotic with transmission to animal handlers reported. Older publications suggest differentiation of BPSV and PCPV can be made based on lesion location,

however cases of BPSV affecting the teats of cattle have been reported. Hence, molecular techniques are required to correctly diagnose these diseases.

Pseudocowpoxvirus

Pseudocowpoxvirus (PCPV) causes vesicular, pustular and scabby lesions most commonly on the teats and udders of milking cows. The clinical signs are often described as an incomplete ring of scabs in the shape of a horseshoe. The disease is mild and rarely of economic importance. PCPV should not be confused with the orthopoxvirus Cowpox virus which causes localised to systemic disease in cats, humans, rats, and other species.

Parapoxvirus of Red Deer in NZ

Parapoxvirus of red deer in NZ (PVNZ) is recognised as a fourth species of PPV after being isolated from lesions on the skin of growing antlers (velvet) of farmed red deer in New Zealand. The disease was originally described on eight farms, and characterised by scabby lesions on the muzzle, lips, face, ears, neck and velvet of farmed red deer. Viruses with strong genetic similarities to PVNZ have been isolated from healthy deer in Bavaria and from proliferative lesions around the mouth of red deer in Italy.

Vaccinia Virus

Vaccinia virus (VACV) is known to have a wide host range but rarely causes severe disease in an immunocompetent host. Sporadic cases of mild VACV infection of cattle (bovine vaccinia) have been reported in the literature for many years, however since the late 1990s bovine vaccinia in Brazil has increased to endemic levels in some regions. Bovine vaccinia presents as papules, vesicles and pustules, leading to ulcers and scabs, on the teat and udders of milking cows and oral cavity of suckling calves. There have been numerous reports of zoonotic transmission of the virus to animal handlers, mainly milking staff who develop vesicopustular and ulcerative lesions on their hands and arms, accompanied by fever, lymphadenopathy and lethargy. The disease can be severe enough to lead to hospitalisation. Human to human transmission of bovine vaccinia appears rare but has been documented.

The pathogenesis of bovine vaccinia is unclear. Experimental intradermal inoculation of cattle with VACV in the skin of the teat showed evidence of local disease and systemic spread, with detection of virus antigen in gastrointestinal-associated lymphoid tissue, and excretion of virus in faeces.

Molecular studies have shown at least two genetically distinct populations of VACV are responsible for the recent epidemic of bovine vaccinia in Brazil. The origins of the two VACV strains are unknown, hypotheses include a derivative of a VACV strain used during the smallpox eradication vaccination campaign in Brazil, or the emergence of a novel orthopoxvirus strain. Surveys of wild and domestic animals in Brazil have found serological and/or virological evidence of orthopoxvirus infection in a wide range of species including horses, rodents and marsupials, dogs, cats and wild-living primates. The role of any of these species in either the re-emergence or persistence of bovine vaccinia is unknown.

A strain of VACV known as buffalopox virus causes sporadic outbreaks of disease in buffalo and, less commonly, in cows in India and other Asian countries. The disease is usually mild, causing typical pox lesions on the teats, udder, and extremities of the head of affected animals.

Cervidpoxvirus

Cervidpoxvirus is a proposed poxvirus genera containing species provisionally named Deerpox virus or Mule deerpox virus. These viruses are associated with mucocutaneous ulcerative lesions in deer that are clinically dissimilar to proliferative PPV lesions. The full genome sequence of an isolate from skin lesions of a free-ranging mule deer has been reported and shown to be genetically distinct from other poxvirus genera. Experimental inoculation of black-tailed deer with an isolate of Deerpox virus resulted in mild clinical disease with gross and microscopic pathology consistent with poxvirus infection (focal to multifocal erythema, papules, pustules, ulcers and scabs), and confirmed by virus isolation. More extensive cutaneous and gastrointestinal lesions caused by Deerpox virus have been reported in captive and farmed white-tailed deer.

Glossary

Arbovirus Viruses that are maintained in nature in transmission cycles between susceptible vertebrate hosts and blood-feeding arthropod vectors.

Arthralgia Pain in a joint.

Autochthonous transmission Spread of a disease within a local population by local arthropod vectors.

Conserved sequence elements (CSEs) Highly conserved genomic elements important for viral replication.

Cytopathic vacuoles Collection of rearranged host membranes and spherules that are a site of replication for alphaviruses.

Spherules Individual plasma membrane protrusions that serve as a site of alphaviral replication.

Sylvatic cycle of CHIKV transmission Transmission between nonhuman primates and *Aedes* species mosquitoes.

Synovitis Inflammation of synovial membranes in the joints.

Urban cycle of CHIKV transmission Transmission within a human population, where humans serve as the vertebrate reservoir and mosquitoes transmit the virus from human to human.

Viremia High presence of virus in the bloodstream; required for the transmission of arboviruses from vertebrate to invertebrate hosts.

Virus-like particles Non-infectious particles composed of viral structural proteins but containing no viral genome.

Classification

Chikungunya virus (CHIKV) is an enveloped virus with a positive-sense, single-stranded RNA genome. CHIKV is classified within the *Alphavirus* genus of the family *Togaviridae* based on its antigenicity, genome sequence and organization, and replication strategy. The *Alphavirus* genus is divided into 7 antigenic complexes; determined by antibody cross-reactivity to the virion glycoproteins E1 and E2, epitopes of which share a high degree of conservation between genetically similar viruses. Along with Bebaru, Getah, Mayaro, o'nyong 'nyong, Ross River, Sagiyama, Semliki Forest (SFV), and Una viruses, CHIKV is a member of the Semliki Forest virus antigenic complex.

Virion Structure

CHIKV particles are 60–70 nm in diameter and composed of an icosahedral nucleocapsid enclosed within a lipid envelope. The capsid is composed of 240 capsid monomers arranged in a $T = 4$ symmetry, and it contains a single copy of the viral genome. The viral envelope is derived from the host cell plasma membrane. Embedded within the viral envelope are 80 trimeric spikes composed of viral glycoproteins E2 and E1. A single spike consists of a trimer of E2/E1 heterodimers, which facilitate viral attachment and entry. Also associated with the E2/E1 complex is E3. During glycoprotein trafficking through the ER-Golgi complex, E3 is covalently bound to the immature E2/E1 dimer, where it aids the folding and association of the dimer; after furin cleavage of E3 in the Golgi, E3 remains non-covalently associated to protect against inappropriate activation of the E1 fusion loop. In the related SFV, E3 dissociates from the E2/E1 complex at neutral pH, however, cryo-EM analysis of infectious CHIKV particles indicates that some E3 is retained in the virion. Also incorporated into CHIKV particles at substoichiometric levels is the structural protein TF, as determined by mass spectrometry of purified virus particles. As TF is produced by ribosome slippage during synthesis of the viral protein 6K and shares the same N-terminus, 6K may also be present at low levels in CHIKV particles.

Genome Organization and Features

The CHIKV genome is a positive-sense, single-stranded RNA of approximately 12 kb in length. Like cellular mRNAs, the CHIKV genomic RNA (gRNA) and subgenomic RNA (sgRNA) possess both a 5' cap and 3' poly(A) tail. The capping and polyadenylation of alphavirus RNAs are mediated by viral proteins and the cap type 0 is different from eukaryotic mRNAs. The first two nucleotides of the genome (AU) are highly conserved within the *Alphavirus* genus, and substitution of these nucleotides inhibits gRNA replication.

The CHIKV genome is organized in a similar fashion to other alphaviruses, consisting of two sequential open reading frames (ORFs), encoding the nonstructural (ns) and structural proteins, flanked by untranslated regions (UTRs) and an internal non-coding region between the two ORFs (Fig. 1). The 5' ORF encodes the ns polyprotein, termed P1234, which is processed by the viral nsP2 protease into 4 mature ns proteins (nsP1 to nsP4). These ns proteins constitute the replicase that synthesizes new viral RNAs. The 3' ORF encodes the structural polyprotein composed of capsid, PE2 (E3 and E2), 6K/TF, and E1. As described in detail

Fig. 1 CHIKV gRNA and sgRNA organization. The CHIKV gRNA serves as a transcript that is translated into the nonstructural polyprotein and a template for negative-strand RNA synthesis. The sgRNA is transcribed from the negative-strand RNA and is translated into the viral structural polyprotein. In addition to the protein-coding regions (indicated in gray), the gRNA and sgRNA encode *cis*-acting elements important for the viral life cycle. To promote translation, both RNAs have a 5' cap and a poly(A) tail. Conserved sequence elements (CSEs) have roles in the evasion of host defense mechanisms, transcriptional enhancement, and transcription of viral RNAs. The packaging signal located within the nsP2 gene promotes encapsidation of gRNAs within the capsid of progeny virions. NsP4 is expressed by a readthrough mechanism of the opal stop codon. Repeat sequence elements (RSEs) at the 3' UTR vary across the CHIKV genotypes in number and length and are important for viral replication.

below, this structural polyprotein is processed by capsid autocleavage and cellular proteases into individual structural proteins that assemble into CHIKV virions.

Protein-Coding Regions

The ns polyprotein is translated directly from the gRNA. A leaky opal stop codon near the 3' end of the nsP3 coding region results in the synthesis of two protein products, P123 and P1234. The structural polyprotein is translated from the sgRNA, which itself is transcribed from the subgenomic promoter active in the negative-strand viral RNA. As described in detail in the viral life cycle section, viral protein expression is temporally regulated by both the continual processing of the ns polyprotein and subsequent synthesis of viral RNA templates.

Non-Coding Elements

In addition to the protein-coding functions of the genome, specific non-coding elements of the alphavirus RNA genome have important roles in genome stability, packaging, viral RNA replication, evasion of host defenses, and host range determination. These activities are mediated by *cis*-acting elements, such as conserved sequence elements (CSEs), packaging signals, and read-through and frameshift elements. The function of these elements is dependent on the secondary RNA structure of the element, the nucleotide sequence, or a combination of both. These *cis*-acting elements are mostly localized to the 5' and 3' UTRs, but some also exist within the protein-coding regions.

There are four CSEs in the CHIKV genome: the 5' CSE, the 51-nt CSE, the sgRNA promoter, and the 3' CSE. These CSEs are highly conserved amongst alphaviruses in both nucleotide sequence and genome location. (1) The 5' CSE of CHIKV and other alphaviruses consists of 60 nucleotides that fold into a stem-loop structure that effectively occludes binding by the mammalian anti-viral protein IFIT1, a key player in the type I interferon-induced antiviral state. Based on studies with Sindbis virus, this stem-loop structure is also critical for RNA synthesis. (2) The 51-nt CSE in the nsP1 coding-region is another *cis*-acting element present in the 5' region of alphavirus genomes, and it forms two stem-loop structures. Both the structure and nucleotide sequence are important for this CSE to act as a transcriptional enhancer. (3) The promoter for the sgRNA is active in the negative-strand RNA, and it overlaps with the nsP4 coding sequence to encompass ~19 nucleotides upstream and 2–5 nucleotides downstream of the sgRNA transcription start-site. Synonymous substitutions at this site inactivate the sgRNA promoter. (4) The 3' CSE consists of 19 nucleotides and is located just upstream of the polyA tail at the 3' end of the CHIKV genome. This element functions as the promoter for negative strand RNA synthesis. Specifically, the last 5 nucleotides of the 3' CSE are required for initiation of negative strand RNA synthesis, where the last nucleotide of the 3' CSE (a cytosine) is the site of transcription initiation. Furthermore, the function of the 3' CSE is complemented by the 5' UTR; as both are required for negative strand synthesis, it is hypothesized that viral RNA replication is assisted by genome circularization.

In addition to the CSEs, the CHIKV genome also contains sequence regions important for genome packaging and viral mRNA translation. A packaging signal located within the CHIKV nsP2 coding region is required for genome encapsidation, and it permits the capsid protein to distinguish gRNA from sgRNA and cellular RNAs. Other functionally important regions of the CHIKV genome dictate nsP4 and TF gene expression. Translation of the gRNA predominately results in the synthesis of P123 instead of

P1234, however, low-frequency read-through of the opal stop codon near the junction of the nsP3–nsP4 coding regions results in the synthesis of P1234. A large stem-loop structure is predicted to be present immediately downstream of the opal stop codon, where it is positioned to promote readthrough events at the nsP3–nsP4 junction. A mutation of the opal stop codon to form an arginine readthrough codon decreased CHIKV-induced disease in a mouse model. The -1 frameshift site (U UUU UUA) within the alphavirus 6K gene is responsible for the expression of the structural protein TF. Most alphavirus sequences downstream of this frameshift site form either an RNA pseudoknot or a hairpin that acts to further stimulate the -1 frameshift. However, the -1 frameshift in CHIKV and other members of the SFV complex appears to be independent of an RNA structural element. Instead, the frameshift is proposed to be stimulated by either the downstream RNA sequence or an unidentified *trans*-factor.

CHIKV 3' UTR

The CHIKV 3' UTR is 498–723 nucleotides long, depending on the strain genotype (CHIKV genotypes are detailed in the Section “Epidemiology”), and is amongst the longest of the alphaviruses. Much of the length of the CHIKV 3' UTR is composed of repeat sequence elements (RSEs), and these vary in both number and length amongst the CHIKV genotypes. In mammalian cells, the third CHIKV RSE serves as a docking site for the cellular HuR protein which protects the viral RNA from degradation. However, most RSEs appear to be insignificant for viral replication in mammalian cells while they are required for optimal viral replication in mosquito cells. In the mosquito cell, the CHIKV 3' UTR RSEs are proposed to contain binding sites for host factors that regulate viral replication in a host-specific manner.

Life Cycle

In general, alphaviruses have a similar life cycle, and much of what is understood of the CHIKV life cycle has been inferred from other alphaviruses. The alphaviral life cycle is generally composed of viral attachment and entry, ns protein expression, viral RNA replication, structural protein expression, and virion assembly (Fig. 2).

Fig. 2 CHIKV life cycle. Upon attachment and endocytosis of CHIKV virions, the viral envelope fuses with the endosomal membrane and releases the gRNA into the host cell cytoplasm. The gRNA is translated to produce the nonstructural polyprotein P1234. *Cis* cleavage of the polyprotein by the nsP2 protease produces a negative-strand replication complex (P123 plus nsP4); leading to the synthesis of negative-strand RNA. The nsP2 protease then further processes P123 to yield a positive-strand replication complex (nsP1 plus P23 and nsP4), which transcribes the positive-strand gRNA and sgRNA. Complete processing of P23 produces the mature replication complex (nsP1, nsP2, nsP3, nsP4), capable of synthesizing positive-strand gRNA and sgRNA. The structural proteins are translated from the sgRNA as a polypeptide. However, capsid self-cleavage during translation yields the capsid and E3–E2–6K–E1 polypeptide. An N-terminal signal peptide in E3 directs the E3–E2–6K–E1 polypeptide into the ER. In the ER, E3–E2–6K–E1 is processed by host signal peptidases to yield PE2 (E3–E2), 6K, and E1. E1 and PE2 associate to form heterodimers. The cleavage of E3 occurs during trafficking in the Golgi complex, but E3 remains non-covalently associated with the E2/E1 heterodimer until their arrival at the plasma membrane. Meanwhile, nucleocapsid cores are formed in the cytoplasm and are transported to the plasma membrane. During budding, progeny virions acquire their E2/E1-studded lipid envelope as they egress from the host cell.

Attachment and Entry

Initial CHIKV attachment to cells can be mediated by virion binding to cellular glycosaminoglycans (GAGs), a family of large, complex polysaccharides (e.g., heparan sulfate) that are present on the cell surface of most mammalian cells. Furthermore, the acquisition of enhanced GAG binding is a common cell culture adaptation of CHIKV and other alphaviruses. Virion-GAG interactions are mediated by residues in the domains A and B of the CHIKV E2 glycoprotein. For example, a mutation of CHIKV E2 domain A amino acid residues 79 and 82 to positively-charged residues enhances virion-GAG interactions, and results in an increased infectivity in cultured mammalian cells and decreased virulence in a mouse model of human disease. CHIKV attachment to cells also can be mediated by phosphatidylserine present in the viral envelope. Cellular phosphatidylserine receptors, such as T cell immunoglobulin and mucin domain-1 (TIM-1), can enhance the entry of CHIKV pseudovirions and virus-like particles in mammalian cells.

Mxra8 was identified as a CHIKV entry receptor in a genome-wide CRISPR-Cas9 screen and the observation was confirmed in both cell culture and mouse models. Mxra8 is a cell adhesion molecule that also serves as a cell entry receptor for several other arthritogenic alphaviruses including Mayaro, Ross River, and o'nyong nyong viruses. It possesses two immunoglobulin-like domains that form three contact points with E2/E1 heterodimers. Another putative mammalian cell entry factor for CHIKV is prohibitin, a multifunctional protein conserved in eukaryotes. Pretreatment of susceptible cells with anti-prohibitin-1 antibodies reduces CHIKV infection, and prohibitin-E2 interactions were shown with colocalization and immunoprecipitation studies. In mosquito cells, ATP synthase and heat shock protein 70 are the only putative CHIKV entry receptors identified to date.

Following viral attachment and entry, cell-bound virus is internalized to release the gRNA into the cytoplasm. The particular details of CHIKV internalization appear to differ based upon cell type and the species from which the cell is derived. However, there are some common features regarding CHIKV internalization, including initial virion uptake by the endocytosis pathways of the host cell and the pH-dependent fusion of the viral envelope with the endosomal membrane. Regarding endocytosis of CHIKV particles, both clathrin-mediated endocytosis (CME) and clathrin-independent mechanisms may contribute. CME is a constitutively active cellular process that involves the formation of clathrin-coated pits at the cellular surface which pinch-off into the cell to form clathrin-coated vesicles containing cargo such as transferrin and low-density lipoprotein. Microscopy studies examining CHIKV particle interactions identified viral interactions with both clathrin and clathrin-coated pits in human and mosquito cells, and selective targeting of endocytosis pathways can differentially affect CHIKV infection depending upon the cell type. Additional cellular factors including Eps15, dynamin, and FUZ can promote CHIKV internalization. Eps15 is required for the formation of clathrin-coated pits and dynamin mediates the pinching-off of endocytic vesicles from the plasma membrane. Each of these proteins can participate in both CME and clathrin-independent entry pathways. Finally, macropinocytosis also may mediate CHIKV internalization in some cells. Given that no study to date has been able to completely block CHIKV infection by targeting a single pathway, it may be that CHIKV particles exploit several cell-mediated internalization pathways to gain entry into host cells.

Following internalization, the virion envelope fuses with the endosomal membrane to release the gRNA into the host cell. Upon endocytosis, cargo is typically delivered first to the early endosome then trafficked to late endosomes and lysosomes. In mammalian cells, CHIKV fusion occurs within Rab5⁺ early endosomes. Viral fusion is a rapid process and can be completed within 40 s of virus particle delivery to the early endosome in mammalian cells. In mosquito cells, CHIKV particles associate with both Rab5⁺ early endosomes and Rab7⁺ late endosomes. Furthermore, knockdown of Rab7 reduces CHIKV infection of C6/36 *Aedes (Ae.) albopictus* cells, implying that viral fusion occurs in late endosomes in mosquito cells. Fusion is driven by the low pH of the endosome, and the differences between fusion in mammalian and mosquito cells may be due to species variation in endosomal pH. The mammalian early endosome has a pH of 6.8–5.5, whereas the pH threshold for CHIKV is pH 6.2–5.9 depending upon the specific virus strain.

In the mammalian early endosome, low pH induces destabilization of the E2/E1 heterodimer and a conformational change in E2 that exposes the buried hydrophobic fusion loop of E1, which mediates membrane fusion. In brief, low pH-induced movement of the alphavirus E2 B domain uncovers the E1 fusion loop, which extends and inserts into the endosomal membrane. This allows E1 to trimerize via interactions between domains I and II of three E1 molecules in the virion spike. Afterwards, E1 domain III refolds, forming a hairpin trimer that forces the viral and host membranes together. A fusion pore forms and releases the nucleocapsid and its packaged genome into the cytoplasm where ns protein expression and genome replication can start. The endosomal membrane fusion is further promoted by the presence of cholesterol and sphingomyelin in the endosomal membrane. In addition, host factor TSPAN9 (tetraspanin 9) can indirectly promote CHIKV and SFV fusion in the early endosome, likely either by recruiting a proviral factor or sequestering an antiviral factor.

Non-Structural Protein Expression and Viral Replication

Alphavirus RNA synthesis is associated with protrusions of the host cell plasma membrane. These rearranged membranes, called spherules, function as replication organelles and are the sites of RNA replication. Each spherule contains a single replication complex, and its formation is dependent on expression of viral nsPs and cleaved nsP4, in particular. nsP3 is hypothesized to contribute to spherule formation through association with host membrane curvature proteins. Later during the infection, individual spherules are endocytosed in bulk to form type-1 cytopathic vacuoles. In SFV, this assembly of cytopathic vacuoles is dependent on an endocytic process requiring PI3K and shuttling along actin and microtubule networks.

Table 1 General CHIKV viral protein functions

Viral protein	Enzymatic activity	Function in CHIKV replication
nsP1	Methyltransferase, guanylyltransferase	5' capping of gRNA and sgRNA; anchors replication complex to membranes
nsP2	Cysteine protease, helicase, NTPase/RTPase	Processing of ns polyprotein; RNA replication; 5' capping of gRNA and sgRNA
nsP3	ADP ribosylhydrolase	Spherule formation; association with host factor FHL1 required for productive infection
nsP4	RNA-dependent RNA polymerase (RdRp), adenylyltransferase	RNA replication; transcription of sgRNA
Capsid	Serine protease	Binds full-length gRNA; oligomerizes to form nucleocapsid
E3	–	Contains signal peptide for translocation of structural polypeptide into the ER; stabilizes E2-E1 heterodimers <i>en route</i> to surface expression
E2	–	Viral attachment protein; virion assembly
6K/TF	–	Stability and infectivity of virions; putative role in mediating membrane permeability, viral budding, and ion channel formation
E1	–	Viral fusion protein

The first genes expressed during CHIKV infection are the ns polyproteins P123 and P1234. The latter is synthesized when the ribosome translating the gRNA reads through the opal codon near the nsP3-nsP4 junction (see above). Read-through to produce P1234 occurs at a low-frequency in alphaviruses, yielding lower quantities of P1234 than P123. During infection, the ns proteins are continuously processed by the nsP2 protease, and the timing and order of this processing regulates the progression of viral RNA synthesis. Upon translation, P1234 is cleaved *in cis* by nsP2 to form P123 and nsP4, which functions as a negative-strand replication complex. The newly synthesized negative-strand RNA is used as a template for both gRNA and sgRNA synthesis by the positive-strand replication complex. The positive-strand complex is produced when P123 is further processed by nsP2 *in cis* and *trans* to yield nsP1, P23, and nsP4. Subsequent cleavage of P23 *in trans* produces the mature replication complex. The mature replication complex is present within hours of infection and is markedly incapable of synthesizing negative-strand RNA. However, complete processing of the nonstructural polyprotein is not required for viral RNA replication.

The individual ns proteins have distinct functions during viral replication (Table 1). The nsP1 protein encodes methyltransferase and guanylyl transferase activities that mediate 5' capping of the positive-sense gRNA and sgRNA. nsP1 also functions to associate the replication complex to host membranes and also may promote CHIKV particle release by downregulating the expression of tetherin, a host antiviral factor that traps virus particles at the cell surface during egress.

As discussed above, nsP2 encodes a protease domain at the C-terminus that is required for the processing of the alphavirus nonstructural proteins. nsP2 also encodes an S-adenosyl-L-methionine (SAM) dependent RNA methyltransferase-like domain at the C-terminus and helicase and NTPase domains at the N-terminus. Both the helicase and NTPase domains play important functions in viral transcription and replication; the former recognizes CSEs important for gRNA and sgRNA synthesis, while the latter modifies the viral RNAs to have a 5' cap. Lastly, some CHIKV nsP2 protein also translocates to the host cell nucleus where it mediates transcriptional shutoff by promoting the polyubiquitination, and consequent degradation, of the RNA polymerase II catalytic subunit RPB1. This effect is mediated by a small, highly variable loop in the nsP2 SAM MTase-like domain.

CHIKV nsP3 has three structural domains: a macrodomain, an alphavirus unique domain (AUD), and a hypervariable domain (HVD). The macrodomain in CHIKV has ADP-ribose hydrolase activity that promotes CHIKV replication and virulence. The AUD is capable of binding zinc, but possible other functions of this domain are presently not known. In contrast to the macrodomain and AUD, the sequence and length of the HVD, as the name implies, is highly variable among alphaviruses. This disordered region serves as a docking site for various host proteins in a virus-specific manner to promote viral replication complex assembly and function. Due to its disordered nature, this region permits large protein insertions, including fluorescent proteins and luciferase. During an infection, nsP3 associates with small, replication complexes at the plasma and endosomal membranes and large complexes associated with the cellular cytoskeleton. The HVD of CHIKV nsP3 also mediates binding with host factor FHL1; not only is FHL1 required for negative strand synthesis, but its expression determines cellular permissiveness for CHIKV. CHIKV nsP3 also sequesters cellular pools of stress granule proteins G3BP1 and G3BP2 and the mosquito homolog, Rasputin, which is important for viral replication complex formation. Other host factors known to interact with the CHIKV HVD of nsP3 include BIN1, CD2AP, MYBBP1A, NAP1L1, NAP1L4, and SH3KBP1.

CHIKV nsP4 is expressed at much lower levels than the other ns proteins due to low frequency readthrough events (discussed above) and N-terminus rule degradation. nsP4 functions as an RNA-dependent RNA polymerase (RdRp) required for the synthesis of viral RNAs. Poor *in vitro* expression of nsP4 has prevented structural studies, but sequence analysis predicts two functional domains. The predicted N-terminal domain is highly disordered and varies between alphaviruses. It is sensitive to point mutations and thought to mediate interactions with other viral and host proteins. The structure of the C-terminal domain is predicted to be similar to other RdRps, and this domain in SINV possesses an adenylyl-transferase activity, suggesting a mechanism for the presence of the poly(A) tail critical for viral RNA stability and function.

Structural Protein Expression and Virion Assembly

The alphavirus structural proteins are expressed from the sgRNA and are initially translated as a polyprotein that is processed to produce five individual proteins (Table 1). The first cleavage of the polyprotein occurs at the capsid-E3 junction, mediated by the protease activity of the capsid protein, and it occurs before translation of the polyprotein is completed. Upon capsid self-cleavage and completion of translation, two structural polyproteins are produced due to a low frequency ribosome slippage causing – 1 frameshift: E3–E2–6K–E1 and E3–E2–TF. E3 contains an N-terminal signal peptide that directs the polyprotein into the endoplasmic reticulum where complete processing will occur by host signal peptidase cleavage at both the N- and C-termini of 6K to yield PE2 (E3–E2), 6K/TF, and E1. E1 and PE2 form noncovalent heterodimers in the endoplasmic reticulum and are post-translationally modified in the Golgi complex. Further processing of PE2 by furin in the Golgi complex produces mature E2 and E3. Following this cleavage, E3 remains noncovalently associated with E2 and prevents premature fusion of the E2/E1 dimers in the low pH of the secretory pathway. Upon arrival at the plasma membrane, E3 can dissociate from the E2/E1 spikes or remain non-covalently associated. Nucleocapsid cores, formed by the oligomerization of capsid protein around a single gRNA, are transported to the plasma membrane. Viral egress occurs via budding, whereby the nucleocapsid cores acquire a lipid envelope decorated with E2/E1 spikes.

Epidemiology

CHIKV is an arbovirus that replicates in mosquitoes and mammals. The primary mosquito vectors that transmit CHIKV to humans are *Ae. aegypti* and *Ae. albopictus*. Adaptation of CHIKV to *Ae. albopictus* is a relatively recent event that arose due to the acquisition of an A226V point mutation in the E1 glycoprotein, and consequently, increases the risk of viral transmission in temperate climates. Transmission cycles of CHIKV can be sylvatic or urban. In the sylvatic cycle, the virus is primarily transmitted between nonhuman primates and arboreal *Aedes* species mosquitoes, and incidental spillovers can cause disease in humans. In the urban cycle, humans serve as the vertebrate reservoir, and mosquitoes transmit the virus from human to human.

Historically, CHIKV was associated with localized outbreaks in Africa and Asia, but due to a dramatic re-emergence in 2004, CHIKV is now found in tropical and sub-tropical areas throughout the world. Phylogenetic analysis of extant strains suggest that CHIKV originated in Africa. The first confirmed epidemic of CHIKV infection in humans occurred in modern-day Tanzania in 1953, and the second recorded epidemic occurred in 1958 in Thailand. In 2004–2005, an outbreak in coastal Kenya spread to islands in the Indian Ocean region that had not previously been associated with CHIKV activity, resulting in hundreds of thousands of infections. In late 2005, CHIKV activity exploded in India, and viremic travelers continued to spread the virus to temperate regions, including Europe. As the virus strain implicated in this epidemic acquired mutations in the E1 and E2 glycoproteins capable of expanding the pool of mosquito vector species, autochthonous transmission was established in the temperate climates of Italy and France. In 2013, CHIKV arrived in the Caribbean region, marking the introduction of the virus to the western hemisphere. CHIKV spread rapidly across the Caribbean region and the Americas, resulting in millions of confirmed and suspected cases. In addition, locally transmitted cases occurred in Florida in 2014.

Prior to 2004, three distinct genotypes of CHIKV had been described: Asian, East/Central/South African (ECSA), and West African lineages (Fig. 3). However, the 2005–2006 outbreak in the Indian Ocean was associated with a new CHIKV sublineage. This Indian Ocean Lineage (IOL) arose from the ECSA genotype, and it is notably characterized by the presence of the E1 A226V mutation in many isolates that increases CHIKV infectivity for *Ae. albopictus* mosquitoes. This point mutation occurred independently in different geographical regions and within different ECSA genetic backgrounds. During the 2005–2006 outbreak, the IOL genotype was globally disseminated by viremic travelers, including its introduction into Southeast Asia. However, the endemic Asian CHIKV strains were not displaced; instead these strains continued to be associated with CHIKV outbreaks in Asia and the Pacific region at the same time. Despite the explosive spread of the IOL/ECSA genotypes, the CHIKV strains that were first identified in the Americas were of the Asian genotype rather than of the IOL/ECSA lineage. Today, most of the CHIKV strains circulating in the Americas phylogenetically form a separate clade within the Asian genotype. However, in 2014 an ECSA CHIKV strain was introduced into Brazil. Given this genotype's previously expanded vector range, it has elicited heightened concern over the risk of CHIKV spread to more temperate areas in the western hemisphere, including the United States.

Clinical Features

CHIKV has an incubation period of 1–12 days, and in most cases, symptoms persist 1–2 weeks (Fig. 4). Unlike most other arbovirus infections, a high percentage (75%–95%) of CHIKV infections are symptomatic. For example, a case-control study during the 2009 epidemic in Thailand found 91% of laboratory-confirmed cases to be symptomatic. The acute disease presents with a sudden high fever, excruciating musculoskeletal pain (including polyarthralgia) in the periphery, headache, and rash; the afflicted joints are typically inflamed. Patients can have a very high viremia (up to 10^9 viral genome copies/mL) and typically remain viremic for about 1 week. In some cases, CHIKV disease is associated with atypical manifestations such as neurological and cardiovascular symptoms and even death in neonates, the elderly, and patients with pre-existing medical conditions.

Fig. 3 *Geography of CHIKV genotypes.* There are three genotypes of CHIKV strains: Asian, East/Central/South African (ECSA), and West African lineages. The geographic distribution of the ECSA and Asian genotypes has expanded dramatically since 2004, likely due to increased intercontinental travel, expansion of the CHIKV mosquito host range, and other factors.

Fig. 4 *Clinical features of CHIKV infection.* Unlike many other arbovirus infections, a high proportion of CHIKV infections are symptomatic. Many infected individuals develop a high titer viremia. The most common signs and symptoms include headache, fever, rash, and polyarthralgia. Symptoms typically appear 1–12 days after infection, and the acute disease can last for 1–2 weeks. Some patients can completely recover after the acute phase of the disease, however, many patients suffer from a subacute and chronic form of the disease. A subacute disease is characterized by the persistence of arthralgia for 3 weeks to 3 months after the initial infection. The chronic form of the disease can include a constant arthralgia over 3 months post-infection or a sudden relapse in clinical disease.

A hallmark of CHIKV infection is the relapse of symptoms or continued symptoms well after the acute infection period has passed. As many as half of all CHIKV patients will relapse or continue to experience arthralgia for weeks, months, or even years after the initial infection. This chronic form of CHIKV disease can be classified into two major types, a musculoskeletal disease and a chronic inflammatory rheumatic syndrome. During the relapse, pain is typically experienced in the same joints that were affected

during the acute phase of the infection, at an equal or a more intense level than previously experienced. The chronic disease form is associated with long-term sequelae, including synovitis and tenosynovitis in the wrists and ankles, joint effusion, and bone erosion/lesions. Analysis of human patients have identified some risk factors for the development of chronic CHIKV disease, which include increased age, severity and duration of initial joint pain, female sex, and pre-existing rheumatologic disease.

Pathogenesis

In vitro, CHIKV is capable of productively infecting various mammalian cells, including those of human, primate, and rodent origin. A study examining CHIKV tropism for human cell types found productive infection of various adherent cells, including epithelial and endothelial cell lines, primary fibroblasts, and primary monocytes and macrophages; but no infection of T and B lymphocytes or monocyte-derived dendritic cells was seen. Productive infection is associated with a cytopathic effect and typically leads to apoptosis of virus-infected cells. Viral replication is completed within 8–16 h post-infection and results in titers of 10^5 – 10^8 PFU/mL depending on the cell type.

In vivo, CHIKV replicates at the site of inoculation in the skin where it predominately targets fibroblasts, but it may also infect resident dendritic cells or macrophages. The virus then disseminates to lymph nodes, spleen, muscles, liver, and peripheral joints where it replicates in connective tissue fibroblasts, skeletal muscle cells, osteoblasts, and possibly in other cell types. During this acute phase of the disease, CHIKV potently induces type I interferon and other proinflammatory cytokines (including IL-1 β , IL-6, IP-10, and RANTES), of which elevated levels have been correlated with increased disease severity in patients and experimentally-infected animals. Virus replication results in musculoskeletal tissue damage and inflammation (including synovitis, tenosynovitis, and myositis) and immune cell infiltration leading to edema and degeneration of cellular and tissue architecture. Various leukocyte populations have been implicated as mediators of CHIKV-induced musculoskeletal tissue pathology in mouse models. Monocyte and neutrophil accumulation in musculoskeletal tissues is associated with CHIKV infection, and disrupting their recruitment to these sites can prevent more severe forms of pathology including the loss of bone. In addition, inoculation of CHIKV into the foot of mice causes a biphasic pattern of swelling with a small peak occurring 2–3 days after the infection and a larger peak occurring at days 6–8 postinfection. This second peak is associated with the influx of CD4⁺ T cells into the foot tissue, and mice lacking CD4⁺ T cells have reduced foot swelling. Thus, although CD4⁺ T cells are required to develop an effective B cell response against CHIKV infection, these cells also exacerbate the joint disease.

Post-acute and chronic CHIKV disease are typically defined as the persistence of disease signs and symptoms from three weeks to three months or for more than three months, respectively, after the acute disease onset. The underlying causes of chronic CHIKV disease are not well understood. The induction of autoimmunity and/or viral persistence in joint tissues have been hypothesized as contributing factors. However, chronic CHIKV disease also could be due to unresolved injury in joint tissue either caused or exacerbated by the acute infection. Animal models have provided evidence of viral persistence associated with chronic synovitis, perhaps as a result of prolonged immune activation. In mice, infectious virus can be recovered from aged mice at 60–90 days post infection, and CHIKV RNA was found in joint-associated tissues and feet up to 16 weeks after the initial infection. A recent mouse study demonstrated that muscle and dermal cells maintain CHIKV infection. In addition, CHIKV RNA can persist in these cells with no detectable surface expression of viral proteins. In nonhuman primates, infectious virus and viral RNA can be recovered weeks post inoculation from joints, muscles, lymphoid organs, and the liver. In aged macaques, RNA can be detected in the spleen as long as 5 weeks post infection. Moreover, CHIKV antigen has been detected in perivascular synovial macrophages and muscle satellite cells in tissue biopsies collected from patients diagnosed with chronic CHIKV disease.

Diagnosis, Treatment, and Prevention

CHIKV infection can be misdiagnosed as dengue due to similarities in patient symptoms and geographic distribution of these two viruses, resulting in an under-diagnosis of CHIKV infection. Key clinical indicators for a CHIKV diagnosis are fever and arthralgia, and studies examining human cases have correlated these symptoms with a 74%–79% positive predictive value and with 73%–84% sensitivity. However, RT-PCR or CHIKV-specific serology is required to confirm a suspected CHIKV infection.

Although studies are underway to identify CHIKV-specific antivirals, there is currently no specific treatment for CHIKV infection. Instead, patients receive general care in the form of anti-inflammatories and analgesics to reduce fever and to alleviate pain and other symptoms. Biological drugs have shown some promise; monoclonal antibodies against CHIKV have been shown to be protective against the disease in nonhuman primates and mice, even when administered at late stages of the infection.

As with treatment, there are no specific prevention measures available against CHIKV. Mosquito control and methods to reduce risk of mosquito bites are the only preventative measures currently available. There is no approved vaccine available, but there are several in clinical trials. The first live, attenuated CHIKV vaccine strain (vaccine TSI-GSD-218; CHIKV strain 181/25) was developed by a serial passage of a clinical isolate in cell culture. The resulting 181/25 strain is immunogenic and protective against CHIKV challenge in animal models. While phase II clinical trials found it to be highly immunogenic, safety concerns regarding bulk production and reversion and instability of attenuation led to its discontinuation. Currently, there are two other CHIKV vaccines in phase II clinical trials: VRC-CHKVLP059-00-VP, a virus-like particle vaccine employing only the CHIKV structural proteins; and MV-CHIKV, another virus-like particle strategy using CHIKV pseudotyped, live-attenuated measles virus vaccine.

Apoptosis Programmed self-induced cell death.

Botryoid Grape-like appearance.

Bursa of Fabricius Specialized organ in birds, that is necessary for B-cell development.

Cryogenic electron microscopy (cryo-EM) Cryogenic electron microscopy is an electron microscopy (EM) technique applied on samples cooled to cryogenic temperatures and embedded in an environment of vitreous water. It is an alternative to X-ray crystallography or NMR spectroscopy for

macromolecular structure determination without the need for crystallization.

Open reading frame (ORF) Open reading frame is the part of a reading frame that has the ability to be translated.

Phylogenetic tree Phylogenetic trees depict the evolutionary relationships among species that are believed to have a common ancestor.

Rolling circle replication (RCR) Rolling circle replication is a process of unidirectional nucleic acid replication that can rapidly synthesize multiple copies of circular molecules of DNA or RNA.

Classification

The family *Circoviridae* was initially established in the mid-1990s and included animal viruses with circular, single-stranded DNA (ssDNA) genomes, distinct from other eukaryotic ssDNA viruses classified at the time. While originally only the genus *Circovirus* was defined, the variability in ssDNA genome sequences and structures prompted the creation of 2 genera (Virus Taxonomy: 2018b Release) within the *Circoviridae* family: *Circovirus* and *Cyclovirus*.

Until 2010, only viral species responsible for relevant disease of avian species and swine were classified within the genus *Circovirus*, with the exception of a non-pathogenic porcine circovirus (PCV-1). However, metagenomic-based studies and degenerate PCR for circoviruses in unconventional hosts have since identified the presence of circovirus genomes in several other species including various other mammals and avian species, freshwater fishes and even ticks. However, the actual host has not been confirmed for some of these newly-detected circoviruses. A caution criterion should be followed, especially when viral sequences were obtained from samples associated to the digestive tract (e.g., feces or pharyngeal/rectal swabs) or from hematophagous parasites (i.e., tick-associated circoviruses) since the detection of viral DNA could be due to an infected meal.

Members of *Cyclovirus* have been described since 2010 in both vertebrates and invertebrates. However, similarly to several circoviruses, a definitive host has been difficult to assign for most, if not all, cycloviruses. In fact, all of them have been identified through metagenomic analysis and degenerate PCR primers. Although they share several genomic features with circoviruses, the putative origin of replication (*ori*), which is marked by the nonanucleotide motif, is located on the Cap-encoding strand in cycloviruses while it is on the Rep-encoding strand in *Circovirus* genus members. Moreover, introns have been identified within Open Reading Frames (ORFs) of several cyclovirus genomes, but not in circoviruses.

Based on genome-wide pairwise identities of Circoviruses and Cycloviruses, a species demarcation threshold of 80% genomic identity, well supported phylogenetically, has been proposed and accepted. Currently, 39 and 48 species have been classified within the *Circovirus* and *Cyclovirus* genera, respectively. ([Fig. 1](#)).

Circovirus tree

Cyclovirus tree

Bootstrap Percentage(BP) ● BP ≥ 90 ○ 70 ≤ BP < 90 ◻ BP < 70

Fig. 1 Maximum likelihood (ML) phylogenetic trees based on the complete genome of members of the viral species within the genus *Circovirus* (top) and *Cyclovirus* (bottom). The ML trees were inferred using Iq-Tree software with the GTR + G + I model of substitution after aligning complete genome sequences using the MAFFT algorithm. Branch support, estimated by 10,000 ultrafast bootstrap replicates, has been categorized and color-coded. The phylogenetic trees were midpoint-rooted.

Fig. 2 Structure of the PCV-2 capsid estimated from cryo-EM of virus-like particles (PDB: 5ZBO). The surface of different capsomers has been colored with different nuances. In transparency, the ribbon structure has been depicted. The surfaces of the subunits constituting one of the pentamer clusters (center of the figure) are color-coded based on the corresponding amino-acid position within the protein. In the right insert, a single capsomer is displayed with the secondary structure highlighted in different colors (i.e., alpha helix and beta-sheets are displayed in red and purple, respectively).

Virion Structure

The virion structure has been accurately characterized for some member of the genus *Circovirus* only, while no morphological data is available for the *Cyclovirus* genus members.

Based on the available evidences, circoviruses are non-enveloped viruses with icosahedral $T = 1$ symmetry. Virion sizes change depending on the viral species, although *Porcine circovirus 1* and 2 (PCV-1 and PCV-2) and *Beak and feather disease virus* (BFDV) virions range from 15 to 25 nm in diameter. A similar viral structure can be expected based on the similarities in the capsid (Cap) protein among members of the same genus. In fact, the crystallographic three-dimensional reconstruction of PCV-2 and BFDV, despite their relative genetic distance (higher than approximately 55% and 65% at nucleotide and protein level, respectively), revealed a common organization, with 60 capsid protein subunits arranged in 12 pentameric clusters (Fig. 2).

The PCV-2 capsid protein is responsible for viral attachment through binding to heparan sulfate (HS) and chondroitin sulfate B (CSB) glycosamino-glycans on the cell surface. A recent structural study based on cryo-electron microscopy (cryo-EM) suggests that each subunit possesses up to five binding sites for heparin but only one can be occupied at a time. Therefore, each capsid might be composed of a unique combination of subunits ligated to heparin. Capsid protein also displays several basic amino acids in the N-terminal region, likely involved in DNA interaction and packaging.

Genome

Recognized members of the family *Circoviridae* are featured by a monopartite ambisense single stranded circular DNA genome ranging from approximately 1.7 to 2.1 kb. Two main ORFs (ORF1 and ORF2), located on different strands in the double-stranded DNA (dsDNA) replicative form, are present in all circoviruses and encode the Rep proteins (encoded by ORF1), fundamental for genome duplication, and Cap protein (encoded by ORF2), the only constituent of the viral capsid.

Although less characterized, other ORFs have been predicted *in silico* in several circoviruses. Unfortunately, experimental confirmation of their actual expression and function are often absent, with the most remarkable exception of BFDV and PCV-2. In the latter, up to 4 additional ORFs have been characterized and associated with several functions, including regulation of cell cycle, apoptosis and immune responses.

Circoviridae genomes display a nonanucleotide motif marking the origin of replication (*ori*). The Rep proteins introduce a nick in the virion-sense strand between positions 7 and 8 of this motif, initiating circovirus genome replication through rolling circle replication (RCR).

The two genera display some differences in the overall genome organization. *Circovirus* display two intergenic regions (IR) between ORF1 and ORF2. Also *Cyclovirus* genomes contain an IR between the 5' ends of Rep and Cap coding ORFs; however, the IR between the 3' ends of these ORFs is absent or significantly smaller than that observed in *Circovirus*. Additionally, as previously mentioned, the putative *ori* is located on the Rep-encoding strand of *Circovirus*, while in *Cyclovirus* is located on the opposite strand.

Life Cycle

Knowledge of the circovirus biological cycle and cell tropism is limited, and essentially obtained through studies on PCV-2.

PCV-2 has been proven to display a wide cell tropism *in vitro* (i.e., PK-15, PEDSV.15, aortic endothelial cells, fetal cardiomyocytes, gut epithelial cells, fibrocytes, monocytes, and a few others) and it is detected in several cells and tissues *in vivo*. However, the capability of each cell to sustain a productive infection is limited and subject of debate.

Likely, epithelial, lymphoblast and monocyte derived cells are the cell-types involved in the PCV-2 life cycle, although with different roles. In fact, while PCV-2 can be abundantly present in monocytes, macrophages and dendritic cells, its replication in these cells, if occurring, is limited. On the contrary, PCV-2 is able to actively replicate in certain subpopulations of lymphocytic cells, and mainly in epithelial cells both *in vitro* and *in vivo*.

Viral binding is mediated by capsid interaction with sulfate-rich glycosaminoglycans like HS and CSB. The internalization process follows different paths depending on the cell line involved, at least in *in vitro* experiments. In the monocytic cell line 3D4/31, the process is clathrin mediated, while in epithelial cells the virus may follow two internalization pathways: a clathrin-mediated one and a dynamin- and cholesterol-independent, but actin- and small GTPase-dependent one. Remarkably, only the latter leads to a full infection. In monocytes, macrophages and monocyte-derived and bone marrow-derived dendritic cells, PCV-2 enters the cell through a mechanism that is not fully characterized. Similarly, virus disassembly and DNA release in the cytoplasm depend on the involved cell line. In the monocytic cell line 3D4/31, it is released at acid pH, while in epithelial cells the process seems to occur at neutral pH. In monocytes, macrophages and monocyte-derived and bone marrow-derived dendritic cells, disassembly appears to not occur. Therefore, the virus can be stored for a long time without replicating in those cells, which likely participate in spreading the virus through the body. After uncoating, viral DNA is transferred to the nucleus, where replication occurs. Since circoviruses do not possess a DNA polymerase, they depend completely on the cell machinery to replicate. PCV-2 DNA replication begins during the first S-phase and depends on both S and G2/M phases of the cell cycle. Viral RNA transcription is mediated by cellular enzymes after ssDNA is converted to dsDNA. The transcription strategy is complex and several RNAs have been detected, although the role of most is unknown. Two Rep proteins (Rep and Rep') are translated from PCV-2 ORF1 RNA. While they share the same 5' end, they have different 3' (Rep' is obtained through alternative splicing). While both proteins display domains involved in RCR and are fundamental for genome replication, some of their other functions are likely different. Additionally, the replicase proteins form homo- and hetero-dimers and the ratio of Rep versus Rep' changes over the course of the infection, suggesting that different protein complexes could have a role in specific reactions. In contrast, only one Rep protein has been identified for other circoviruses.

DNA encapsidation occurs in the nucleus and virions are released into the cytoplasm by budding. Viral factories observed in the cytoplasm are bounded by multiple membranes, suggesting that the rough endoplasmic reticulum (RER) or Golgi apparatus may play a role in virion assembly. Clusters of viral particles, potentially moving from organelle membrane to the cytoplasm in the final replication stages, are then released from the plasma membrane by exocytosis or by budding from the cell membrane. Finally, an increase in cell death during the last hours of infection coupled with the presence of large clusters of virions forming paracrystalline arrays suggests that cell lysis could be another path for virus release.

Knowledge of other circovirus life cycles is essentially absent; however, the genome and protein resemblance, coupled with some similarity in the involved tissues and induced lesion (when present), could suggest a similar cycle.

No consistent data are currently available on the biological cycle of cycloviruses. Since the putative cyclovirus *ori* and predicted Rep share conserved features with members of the genus *Circovirus*, cycloviruses are also thought to replicate through RCR.

Epidemiology

The first *Circovirus* (later renamed PCV-1) was recognized in the 70s as a contaminant of porcine kidney cell lines. Thereafter, other circoviruses (i.e., BFDV, *Pigeon circovirus* (PiCV) and *Goose circovirus* (GoCV)) associated with clinical syndromes were reported in avian species in the 80s. However, despite overt clinical signs, the economic impact of these diseases remained limited. In the middle 90s, a dramatic change occurred with the emergence and discovery of PCV-2 as one of the most devastating viral diseases of the swine industry. This event drew attention towards this group of viruses. Since then, many *Circovirus* members have been reported in other avian and mammalian species (Fig. 1). Noteworthy, in most instances, no association with clinical signs could be demonstrated. *Canine circovirus* (CanineCV) and *Porcine circovirus 3* (PCV-3) are two potential exceptions since some evidence of their potential role in overt clinical syndromes has been reported.

Similar conclusions can be drawn for *Cyclovirus* members. Although some of these viruses were initially recognized in diseased subjects, including human beings, no causal association could be consistently established. Moreover, the actual host tropism is poorly known for most of them due to the lack of viral isolation and experimental models. In addition, several *Cyclovirus* DNAs have been detected and characterized from feces or digestive tract samples, which hinders the differentiation between contamination and actual infection.

Paleovirology studies, investigating the presence of sequences related to circoviruses integrated in the genome of vertebrate species, suggest that the origin of this virus family may exceed 40–50 million years. Therefore, the very recent discovery of new species is likely attributable to the improved identification and diagnostic capabilities. However, at least in some instances, other factors likely played a role in the emergence and expansion of these viruses. PCV-2 is a particularly illustrative example.

Retrospective studies demonstrated its presence in archived samples since 1962 and molecular clock-based studies dated it back at least at the beginning of the 20th century. Consequently, the switch from an apparently subclinical infection to a clinical one was likely due to the modern intensive farming conditions, which provided several cofactors (i.e., high animal density, stressing factors, management and husbandry related factors, co-infections, etc.) that enhanced viral replication and lead to signs and lesion appearance. A differential susceptibility of particular genetic lines of commercial pigs also seems to be involved. Finally, the evolution and adaptation of the virus is likely, as suggested by the emergence of new strains and genotypes over time, characterized by a partially different virulence and immunological features.

The multifactorial nature of PCV-2 disease is supported by the frequent subclinical course of the infection and by the evidence that PCV-2 alone is typically not sufficient to cause disease under experimental conditions. A comparable scenario could be true for PCV-3, a virus that likely circulated in the swine population for decades and is now frequently detected in both symptomatic and asymptomatic animals. Even in non-intensively raised species like dogs and psittacine birds, CanineCV and BFDV infection can be detected both in severely ill and healthy subjects. The reasons behind this behavior are not fully understood. If a similar picture can be expected for other *Circoviridae* remains to be established.

Unfortunately, most *Circovirus* and *Cylovirus* species have been detected only one or a few times. Therefore, data on their prevalence and distribution are largely lacking. The species for which adequate epidemiological and molecular epidemiology data are available, like BFDV, PCV-1, PCV-2, PCV-3, Duck circovirus (DuCV), GoCV and CanineCV, display a worldwide distribution with an absent-to-limited geographic clustering. However, these viruses affect domestic animals and their spreading patterns appear deeply connected to animal trade and movements. A different pattern could characterize circoviruses infecting wild species only. Significantly, some human cycloviruses initially considered to be limited to certain areas have demonstrated a wider geographic distribution than originally thought.

Circoviruses were traditionally thought to have a narrow host range. Nevertheless, even if a “preferred” host can be identified, sporadic detection in other species is described with increasing frequency. PCV-2 has been detected in wild boars, feral pigs, peccaries, but also in mice (used as experimental models) and rats (especially captured on commercial swine farms), ruminants and in fur animals (minks, foxes and raccoon dogs). Similarly, PCV-3 was detected in cows, dogs and laboratory mice, as well as in wild animals including wild boar, chamois, roe deer and related ticks. The actual clinical impact and epidemiological role of those hosts remains unclear, with the only exception being wild boars whose high PCV-2 and PCV-3 infection frequency suggests they could be a PCV reservoir in nature. The close genetic similarity between strains detected in wild boar and domestic pigs testifies to a frequent strain exchange between these populations, although the directionality of the viral flux is still unknown.

Detection of CanineCV in significant numbers of wild carnivores, including foxes, wolves and badgers, has been described, sometimes even with the presence of clinical signs.

As a group, ssDNA viruses are considered to be rapidly evolving organisms, characterized by a substitution rate comparable to that of RNA viruses. Although few studies have been performed on circovirus evolution, they seem to make no exception. A certain heterogeneity in evolutionary rate characterize different species. For example, PCV-2 substitution rates approach 10^{-3} substitutions/site/year, while that of PCV-3 is about two orders of magnitude lower. A similar slower rate evolution was also estimated for PCV-1. Detailed studies explaining such differences are still lacking, but a combination of higher population size and stronger selective pressures imposed by the host could play a pivotal role. Within-host viral variability has been investigated for PCV-2 only, revealing the emergence of several subpopulations over the course of infection. Significantly, the higher within-host variability was observed in the capsid coding region, suggesting the immune response as one of the major drivers of viral evolution. A comparable tendency has been described at a population level, where the capsid coding gene is the most variable and the one under stronger selective pressure. Importantly, evidence of vaccine-driven immune-selection have been provided and the emergence of multiple genotypes (i.e., cluster of strains with an independent evolution) alternating over time is partially due to an escape from the herd immunity developed against previously circulating genotypes.

In addition to mutation, frequent recombination has been reported within *Circovirus* member species, occurring especially in the intergenic regions. Epidemiological studies performed on PCV-2 have confirmed that recombination is a common phenomenon both within and between genotypes and demonstrated that recombinant viruses can have an evolutionary success comparable to parental ones.

Viral persistence, shedding and infection routes have been investigated for a limited subset of circoviruses. Oronasal is the primary route of PCV-2 transmission, which was detected in most animal secretions and excretions, including saliva, nasal, tonsillar, bronchiolar and ocular secretions, milk, colostrum, semen, feces and urine. Vertical, transplacental infection can also occur. Even though experimental studies have not been performed for PCV-3, virus detection in the same excretions, secretions and in aborted fetuses suggests similar transmission modes. Orofecal transmission is likely for CanineCV. Horizontal transmission occurs for BFDV, PiCV, DuCV and GoCV, even though vertical transmission cannot be excluded; in fact, vertical transmission has been suggested for PiCV.

Clinical Features

Circoviruses have been detected in the presence of several clinical syndromes in different species. However, a consistent association between infection and emergence of overt clinical signs is often lacking. Moreover, even when a causal nexus has been inferred, circovirus diseases are typically multi-factorial, infection being necessary but not sufficient to induce disease.

PCV-2 is the most studied pathogen belonging to this family and represents an illustrative example. PCV-2 seroprevalence suggests that PCV2 infection is ubiquitous all over the world and most pigs come in contact with the virus during their life. Nevertheless, morbidity is much lower and variable among countries, farms and over time. Even if most of infections remain subclinical (PCV-2-SI), their relevance cannot be ignored since even asymptomatic cases have been associated to a decrease in productive performance.

A number of clinical syndromes have been linked to PCV-2 infection, collectively named porcine circovirus diseases (PCVD). These can be broadly divided in systemic diseases and organ specific ones, although the differentiation can be only effectively made at a histological rather than clinical level. PCV-2 systemic disease (PCV-2-SD) is characterized by wasting or weight loss, pallor of the skin, respiratory distress, diarrhea, low grade fever and occasionally icterus. Enlarged subcutaneous lymph nodes are also a common finding. The onset of disease may be acute, leading to death within a few days in some pigs while others display a more chronic course and fail to gain weight or thrive. Morbidity in affected farms can reach 4%–30% (with a sporadic higher peak) and mortality ranges from 4% to 20%. PCV-2 lung disease (PCV-2-LD) and PCV-2 enteric disease (PCV-2-ED), postulated once as independent entities, are now believed to be part of PCV-2-SD. The frequent presence of co-infections and the role of PCV-2 in porcine respiratory disease complex (PRDC) further complicates the clinical scenario. PCV-2 is also involved in reproductive disease (PCV-2-RD), leading to mummifications, late term abortions and stillbirths. Return-to-estrus might also be linked to early embryo infection. However, the relevance of PCV-2-RD is apparently low under field conditions, likely because of the high seroprevalence and presumably immune coverage in adult sows. Actually, PCV-2-RD affected herds are typically start-up herds with high number of gilts or PCV-2 seronegative herds. Porcine dermatitis and nephropathy syndrome (PDNS) has also been linked to PCV-2 infection, although the role of PCV-2 in pathogenesis is debated. The most evident sign is the presence of irregular, red-to-purple macules and papules in the skin, primarily on the hind limbs and perineal area, but sometimes with a broader distribution, which over time evolve to dark crusts. The disease prevalence is low (less than 1%), but the lethality can reach 50%–100%. Pigs typically die within a few days after the onset of clinical signs due to acute renal failure while the survivors recover in 7–10 days.

Similar clinical symptoms have been described in PCV-3 infected pigs, including PDNS, reproductive disorders, enteric and respiratory disease. Nevertheless, PCV-3 is often detected in healthy animals. To date, high amounts of PCV-3 have been found in few cases of reproductive disease and nursery pigs with periarteritis and myocarditis.

CanineCV was initially identified in dogs with vasculitis and/or hemorrhagic gastroenteritis in the United States. Over time, it has been reported in several countries in presence of enteric signs, such as vomiting and diarrhea with hematochezia, and lymphadenitis. CanineCV has also been identified in histological lesions of the cerebrum from foxes with neurological disorders.

Among avian species, psittacine BFDV is probably the most relevant. Like in PCVDs, mortality and clinical signs in birds infected with BFDV are variable and dependent on the species of bird, age at the time of infection, presence or absence of concurrent infections and possibly the viral strain involved. Typically, the disease is detected in young birds of less than 3 years and is clinically characterized by a chronic, progressive loss of feathers, and, in some species, deformities in beak and claw. The infection can last for years; however, more often the animals die after some months due to secondary infections, since the condition causes an immunosuppressive state.

Circoviral infection in pigeons is associated with high morbidity and low mortality in most disease outbreaks. A broad range of signs and severity is observed in infected pigeons, including poor performance, diarrhea, and ill thrift.

Circovirus particles were detected in a canary affected by a condition known as “black spot”, which is associated with abdominal enlargement, gall bladder congestion, failure to thrive, dullness, anorexia, lethargy, and feather disorder. Growth retardation, feathering disorders and increased losses have been reported in circovirus-infected geese. Clinical signs of circovirus infection in Mallard ducks include feather dystrophy along the dorsum (hemorrhagic shafts) and poor body condition with low weight gain. In one report, circovirus infected finches displayed nasal discharge, dyspnea, anorexia, and depression.

A brief summary of most relevant clinical signs associated to circovirus infection are reported in [Table 1](#).

The clinical role of circoviruses is essentially unknown. Of note, CyCVs have been detected in cases of respiratory, enteric and neurological infections in humans and the presence of the virus has been found in serum, stool or cerebrospinal fluid (CSF) of patients with acute flaccid paralysis, paraplegia or suspected central nervous system infections. However, a causal association has not been proven.

Pathogenesis

Most circoviruses are considered able to cause disease in their corresponding hosts under certain conditions (not always well determined), although the majority of infections end up with subclinical scenarios. Circoviruses mainly replicate in epithelial and/or endothelial cells and, to a limited extent, in immune cells such as macrophages and lymphocytes. These animals developing clinical disease tend to suffer from immunosuppression and damage in the lympho-reticular tissues.

Among avian circoviruses, pathogenesis is mainly inferred from the knowledge generated on BFDV. This virus is considered to be epitheliotropic, targeting the basal epithelial layer of the feather and feather follicles. In fact, it is possible to detect circovirus-specific intranuclear inclusions in these cells, which are actively dividing. BFDV inclusions are also present in the cytoplasm of macrophages; although it has been suggested that most of the accumulated virions in the inclusions are due to the phagocytosing

Table 1 Summary of the main criteria to diagnose the well-recognized circoviral diseases in different animal species

Disease	Diagnostic criteria ^a		
	Clinical signs and gross pathology	Histopathology	Viral detection
PCV-2-systemic disease (PCV-2-SD)	Wasting Lymphadenopathy Interstitial pneumonia	Moderate to severe lymphocyte depletion with granulomatous inflammation of lymphoid tissues	Moderate to high amount of PCV-2 in lymphoid tissues by IHC/ISH ^b
PCV-2-reproductive disease (PCV-2-RD)	Abortion Mummified fetuses Weak-born piglets Myocardial necrosis	Necrotizing and fibrosing myocarditis	Moderate to high amount of PCV-2 in myocardium by IHC/ISH
PCV-2-subclinical infection (PCV-2-SI)	No clinical signs Lesser average daily weight gain	None or mild lymphocyte depletion with or without mild granulomatous inflammation of lymphoid tissues	Low amount of PCV-2 in tissues by IHC/ISH (or lack of PCV-2 in tissues by IHC/ISH but positive PCR)
Porcine dermatitis and nephropathy syndrome (PDNS)	Skin red papules and macules Kidney generalized petechiae Nephromegaly	Fibrinous-necrotizing glomerulonephritis Systemic necrotizing vasculitis	PCV-2 definitive causality on PDNS has not been demonstrated, so, its detection is not yet part of the diagnostic criteria
PCV-3 associated disease ^c	Abortion Mummified fetuses Weak-born piglets Congenital malformation	Non-suppurative systemic perivascularitis Non-suppurative myocarditis	Moderate to high amount of PCV-3 by ISH or low Ct values for qPCR ^d
Canine circovirus infection	Bloody diarrhea Vomiting Hemorrhagic enteritis	Systemic vasculitis Intestinal crypt necrosis Lymphocyte depletion of lymphoid tissues	Moderate to high amount of canine circovirus in tissues
Mink circovirus infection	Diarrhea Loss of feathers	Gastro-enteritis Epidermal cell necrosis, epidermal hyperplasia and hyperkeratosis	Amount of virus not defined to establish a diagnostic criterion
Beak and feather disease (BFD)	Deformity of the beak Deformity of the claw	Macrophage intracytoplasmic inclusions in affected epidermis and feather pulp	Moderate to high amount of BFDV by ISH or qPCR in tissues
Pigeon circovirus infection	Increased rearing losses Atrophy of thymus and bursa of Fabricius	Follicular hyperplasia and mild lymphocyte necrosis to lymphocyte depletion and histiocytosis Macrophage intracytoplasmic inclusion bodies	Moderate to high amount of PiCV by ISH or qPCR in tissues
Duck circovirus infection	Feathering disorders Growth retardation and low body weight	Lymphocytic depletion, necrosis, and degeneration of lymphoid tissues	Moderate to high amount of DuCV in tissues by qPCR
Finch, goose, gull and canary circovirus infections	Poorly described, but mainly growth retardation and low body weight in all these species	Lymphocytic depletion and necrosis of the bursa of Fabricius Macrophage intracytoplasmic inclusion bodies	Not well established criterion; presumed, moderate to high amount of these viruses

^aclinical signs and gross lesions are indicative; the final diagnosis is established by means of histopathology and virus detection.^bimmunohistochemistry/*in situ* hybridization.^calthough not yet clarified, PDNS has also been linked to PCV-3 infection.^dquantitative PCR.

activity of these cells rather than from endogenously replicated virus. The mechanism by which lymphoid organs such as the thymus and bursa of Fabricius become depleted in clinically affected birds is not entirely clear; it has been speculated that an indirect mechanism involving a cytokine-mediated reduction in lymphocyte differentiation might happen. Lymphocyte depletion is probably transient in subclinically infected animals, but persistent in diseased birds. Therefore, BFD-affected birds are susceptible to opportunistic secondary bacterial, chlamydial, and fungal infections.

Pathogenesis of circovirus infection in mammals has been documented more thoroughly than that of avian viral species. Specifically, the vast majority of data derives from PCV-2, the most studied *Circoviridae* family member, which has been associated with a number of economically significant diseases (PCVD). The greatest amount of PCV-2 is found in the cytoplasm of monocyte/macrophage lineage cells, both in PCV-2 diseased and subclinically infected pigs. *In vitro* studies have shown that PCV-2 is able to infect these cells, persisting for extended periods of time with apparently no or minimal active replication. Therefore, monocytic

Fig. 3 Schematic representation of the pathogenesis of PCV-2 infection in post-natal swine. Adapted from: Porcine circovirus type 2: the virus, the disease and the vaccine, from Segalés, J. Grupo Asís Biomedica S.L., 2017.

cells seem not be the primary target for PCV2 replication and may represent a dissemination mechanism for PCV-2 throughout the host. Moreover, PCV-2 causes impairment of dendritic cell (DC) functionality *in vitro*, which may alter innate and virus-specific immune responses. However, *in vivo* information about these effects is minimal.

Cell types that supports PCV-2 replication *in vivo* are not completely elucidated. Initial work suggested that macrophages and lymphocytes did not play a significant role in PCV-2 replication, but subsequent research indicated that those cells types (mainly macrophages) may support replication to a certain degree. Ultrastructural studies in cell culture and lymph nodes from PCV-2-SD affected pigs have suggested that mitochondria may play a role in PCV-2 replication. Further characterization of PCV2-infected leukocyte subpopulations from peripheral blood mononuclear cells (PBMCs) indicated that mainly circulating T ($CD4^+$ and $CD8^+$) and potentially B lymphocytes, support PCV-2 replication; PBMC-derived monocytes apparently do not. PCV-2 also replicates in fetal myocardiocytes in experimentally infected porcine fetuses and in zona pellucida-free morulae and blastocysts.

Fig. 3 displays a proposed scheme for the post-natal pathogenesis of PCV-2 infections. PCV-2 viremia is first detectable around 7 days post-inoculation (PI), and viral load increases and reaches a peak between days 14 and 21 PI. Around 10–14 days PI, seroconversion against PCV2 is usually detected, especially if pigs remain subclinically infected. Under field conditions, the most likely age of infection is at the late nursery period and sero-conversion consequently occurs around 7–12 weeks of age; antibodies may last at least until 28 weeks of age. However, PCV-2 infection can occur at any age, and so evidence of infection and/or sero-conversion must be monitored by means of viral detection (usually PCR or quantitative PCR) and/or serological (mainly ELISAs) tests, respectively. Besides its detection in serum samples, PCV-2 can be detected in several organs, with lymphoid tissues containing the highest viral loads. PCV-2 amounts measured by quantitative PCR methods are usually 2–4 logs higher in lymphoid tissues compared to serum. The virus can be detected in virtually all tissues of a viremic pig. Immunohistochemistry and *in situ* hybridization techniques have shown presence of PCV-2 in epithelial cells from the kidney and respiratory tract, endothelial cells, lymphocytes, enterocytes, hepatocytes, smooth muscle cells, and pancreatic acinar and ductular cells.

The capacity of a pig to mount an adaptive immune response is key to prevent the progression of PCV-2 infection towards PCV-2-SD (**Fig. 3**). The onset of PCV-2 antibodies is followed by a decrease of viral loads and, eventually, resolution of viraemia. Long-lasting PCV2 viraemia and/or detection of PCV-2 in tissues, however, has been described in experimentally subclinically infected pigs despite the presence of high PCV-2 antibody titers. Inefficient humoral responses and, in particular, a poor PCV-2-neutralizing antibody response, are linked to increased viral replication, which results in severe lymphoid lesions and PCV-2-SD (**Fig. 3**). Under field conditions, from lactation to the growing-finishing period, the proportion of PCV-2 infected pigs and viral loads increase gradually, coincidentally with the waning of maternal-derived immunity.

Porcine embryos are susceptible to PCV-2 infection and their susceptibility varies with developmental stage. Virological and clinical outcomes of direct intra-fetal inoculation of PCV-2 at 57, 75 and 92 days of gestation have been described. At 21 days post-infection it was found that PCV-2 replicated in all inoculated fetuses but virus replication was significantly higher in fetuses inoculated at 57 days of gestation. In such fetuses, the heart displayed myocarditis-like lesions and harbored the highest virus load and number of infected cells. Fetuses inoculated at 75 days of gestation were stillborn at birth, while fetuses inoculated at 92 days of gestation did not show any lesion at birth. Fetuses inoculated at 75 or 92 days of gestation, but not the fetuses inoculated at

57 days, had antibodies against PCV-2 at delivery. PCV-2-infected cells identified in fetuses inoculated at different stages of gestation include cardiomyocytes, hepatocytes and cells of the monocyte/macrophage lineage.

Intranasal inoculation of pregnant sows or artificial insemination with purposely contaminated semen have also caused PCV-2 infection of fetuses/newborn piglets and reproductive failure. In contrast, sows artificially inseminated with semen of boars experimentally infected with PCV2 did not cause reproductive problems or infection of dams. Therefore, it is believed that the amount of PCV-2 naturally shed in boar semen is not sufficient to infect sows or their fetuses.

Little is known about the pathogenesis of PDNS, but it has been suggested that excessive PCV-2 serum antibody titers may be linked with the triggering of the condition. This hypothesis still awaits experimental confirmation: to date, studies on tissue sections from pigs with PDNS have failed to consistently demonstrate PCV-2 antigen or nucleic acid associated with PDNS lesions. Therefore, PCV-2 causality of PDNS is mainly based on circumstantial epidemiological and pathological evidences, but there is no experimental demonstration of such causation.

No data is currently available regarding the pathogenesis of PCV-3 infection. The first lesion descriptions associated to PCV-3 resembled those traditionally described for PCV-2-SD and PDNS, including as well myocarditis and systemic inflammation. The latest reports have emphasized the presence of PCV-3 genome mainly in inflammatory infiltrates in animals displaying perivascular inflammation at a systemic level, affecting especially kidney, liver, lymph nodes, lung and brain. Moreover, viral nucleic acid has also been found in follicular areas of lymph nodes, but usually in a low amount, similar to the location and distribution observed in pigs subclinically infected by PCV-2. Detection of the virus in tissues of stillborns and pigs with congenital anomalies points to a potential role in reproductive disease and, therefore, vertical transmission as an important route of dissemination.

Little is also known about the pathogenic role of CanineCV. On postmortem examination, some infected dogs showed histological lesions of necrotizing vasculitis and hemorrhage throughout the gastrointestinal tract, as well as granulomatous lymphadenitis of the lymph nodes. By *in situ hybridization* (ISH) analysis, abundant cytoplasmic viral nucleic acid has been detected in macrophages and monocytes in lymphoid tissues, including germinal centers and subcapsular and medullary sinuses of lymph nodes and ileal Peyer's patches. However, CanineCV has been detected in feces of healthy dogs and dogs with hemorrhagic diarrhea with a similar frequency. Therefore, CanineCV does not seem to be involved as a primary agent in dogs, and other co-factors might be necessary to elicit disease, similarly to other circoviruses.

The pathogenesis of cyclovirus infections is virtually unknown. All viruses of this genus have been detected in a number of samples by means of metagenomics and degenerate PCR methodologies, without an apparent association to a particular disease or condition. In fact, such detection has usually focused on the virome in the vertebrate and invertebrate species where they were detected. So far, the meaning of cyclovirus detection under disease scenarios is purely speculative. Importantly, techniques able to detect cycloviruses *in situ* in tissues or their putative humoral and cellular immune responses are still lacking.

Diagnosis

Diagnosis is the investigation or analysis of the cause of a condition, situation, or problem. Regarding *Circoviridae* family members, the terminology diagnosis should be applied at two major levels: identification of a disease problem (causal association of the agent with the condition) and identification of an agent, its components or antibodies against it. Taking into account the ubiquitous distribution of circoviruses and cycloviruses, disease causality is difficult to be established since in most of the cases a multifactorial origin is involved. Moreover, for just a limited number of circoviruses (but not of cycloviruses), a relatively consistent association with disease has been demonstrated (Table 1). The consistency of the association between infection and clinical disorder has been established using three main criteria: presence of compatible clinical signs, characteristic gross and histopathologic lesions, and presence of the virus (ideally by immunohistochemistry and/or *in situ* hybridization methods) within the lesions.

The most studied diseases have been by far PCVDs caused by PCV-2 and BFD caused by BFDV. In both cases, a significant clinical problem was first detected in swine and psittacine birds and the agent was subsequently discovered. Relevant gross and microscopic lesions were described in both diseases, being lymphocyte depletion and granulomatous inflammation of lymphoid tissues together with the presence of intracytoplasmic botryoid inclusion bodies common and very characteristic hallmarks. These histopathological lesions were subsequently confirmed in a number of circoviral infections in avian species (i.e., pigeon and geese). Importantly, avian circoviral diseases have been also associated to chronic, progressive loss of feathers, and, in some species, deformities of the beak and claws. The key diagnostic aspects of circoviral diseases are summarized in Table 1.

Techniques able to detect the viral antigen or nucleic acid within tissues displaying histopathological lesions are key to establish a sound diagnosis of disease. Immunohistochemistry (IHC) and ISH methodologies have been successfully developed to detect a number of circoviruses. Most of the techniques have been used to investigate the viral tropism for pathogenesis research purposes. Nevertheless, a routine diagnostic activity using IHC or ISH is performed only on a limited number of circovirus infections of clinical relevance such as PCVDs and BFD.

The study of *Circoviridae* family members has benefited enormously from the development of molecular techniques. As previously mentioned, *Cycloviruses* and most of *Circovirus* species have not been isolated yet. Therefore, the identification of their genome represents the only proof of their existence. In consequence, care must be taken in terms of interpretation of a given result.

A positive result indicates the presence of nucleic acid of the virus in a sample but does not provide any clue about the effects of the agent on the vertebrate/invertebrate animal. Quantification of the genome implies a further step, since the amount of genome for a number of circoviruses has been correlated with disease occurrence. However, the number of genome equivalent copies is also difficult to interpret for these agents that have never been associated with a certain disease. Taking into account that their infection dynamics are unknown and a particular amount of nucleic acid for clinical infections versus being part of the normal virome has not been established, the significance of their presence is still to be established.

A number of laboratory techniques have been developed to detect antibodies against circoviruses (not yet against cycloviruses). Some techniques such as the immunofluorescent antibody test and the immunoperoxidase monolayer assay have been used mainly in research, but implied the availability of a viral isolate, which limited their use almost exclusively for PCV-2. The development of ELISA tests using recombinant proteins widened the possibility of detecting antibodies against different circoviruses, such as PCV-2, BFDV, PiCV, GoCV, DuCV and mink circovirus (MiCV). However, only PCV-2 ELISA commercial kits are currently available for routine diagnosis. No serological tests have so far been developed for the detection of antibodies against cycloviruses.

Disease Control

Control of circoviral diseases have been mainly focused on counteracting the specific clinical signs of pet animals by means of supportive treatments. Importantly, these signs can vary greatly among individuals due to the immunosuppressive nature of the disease in clinically affected animals.

The initial control strategies for livestock species, mainly against PCV-2-SD, were developed to counteract the different infectious and non-infectious risks or triggering factors for the development of clinical disease. Noteworthy, most of the implemented measures were based on empirical results and not on contrasted and fully demonstrated efficacy. Overall, efforts were mainly directed to diminish/control the concomitant microbiological burden, decrease viral transmission and potentiate resistance against disease. Among these measures, the Madec's 20-point plan (a list of general zootechnical actions to lower the impact of disease) was the most practiced one, since they significantly decreased the percentage of mortality in severely affected farms. These measures were designed to reduce the infection pressure of PCV-2 as well as other infections, improve hygiene and reduce stress at different production stages.

The advent of commercial PCV-2 vaccines radically changed the clinical situation regarding PCV-2-SD and allowed the discovery of the so-called PCV-2-SI. The excellent efficacy of PCV-2 commercial vaccines surpassed the most optimistic expectations, to the point that nowadays it is the most used swine vaccine in the worldwide market. PCV-2 vaccines allowed a decrease in the impact of clinical signs and mortality, and more homogeneous animals in terms of body weight and improved average daily weight gain. Importantly, several commercial vaccines have appeared in the market and the different meta-analyses published on the subject indicated no significant differences in their efficiency to control PCV-2-SD and a significant impact for all the products when compared to non-vaccinated animals.

The most widely used vaccination scheme includes the use of the commercial products in piglets around weaning, using one (most often) or two doses. Also, several vaccines have been licensed to be applied in sows, which have been used to prevent PCV-2-SD in piglets (sows/gilts are vaccinated at the end of gestation) or to potentially prevent PCV-2-RD (sows/gilts are vaccinated pre-mating).

So far, no commercial vaccines are available for other circoviral diseases. Although the lack of virus isolates may potentially jeopardize initial testing of potential vaccine prototypes, most of the experimental work is performed with recombinant proteins derived from the sequences of the Cap gene from circoviruses. Using this approach several vaccine prototypes have been developed against some avian circoviruses and tested under experimental conditions. Such developments include prototypes against BFDV, DuCV and PiCV.

No vaccine products have been developed against the rest of circoviruses, mainly because they do not represent a significant threat to the corresponding infected animal populations. Also, it is not expected that vaccines will be developed against cycloviruses since their association with disease outcome is still to be demonstrated.

Conclusions

The number of family *Circoviridae* members has been significantly expanded in the last 10 years, and the novel taxonomy implied the removal of the genus *Gyrovirus* and the addition of the genus *Cyclovirus* together with the genus *Circovirus*. A number of circovirus species are unequivocally linked to clinical disease in animals, mainly in pigs and birds, although the associated disorders are of multifactorial nature. A common denominator of these conditions is the affection of the immune system of the animals, leading to immunosuppression in severely affected ones. Curiously, a large number of circoviruses and all known cycloviruses to date have never been isolated, and the only evidence of their existence is genome detection. Contrasting with the simplicity of these viral genomes is the complex and still poorly understood pathogenesis. Progress in molecular biology techniques and phylogenetic studies will surely facilitate elucidating evolutionary relationships among classified as well as newly identified members of the family *Circoviridae* in the future.

Glossary

Infectious clone A full-length DNA copy of an RNA virus genome from which full-length viral RNA can be generated, leading to production of infectious virus.

Nidovirales (nidoviruses) An order comprising positive-sense RNA coronaviruses, toroviruses, arteriviruses, and roniviruses that have a common genome organization and expression, similar replication/transcription strategies, and

form a nested set of 3' co-terminal subgenomic mRNAs (*nidus*, Latin for nest).

Ribosomal frameshifting Movement (shift) backward by one nucleotide of a ribosome that is on an RNA, caused by particular RNA structures and sequences. Subsequent continuation of the progress of the ribosome is in a different open reading frame.

Introduction

Coronaviruses are known to cause disease in humans, other mammals, and birds. They cause major economic loss, sometimes associated with high mortality, in neonates of some domestic species (e.g., chickens, pigs). In humans, they are responsible for respiratory and enteric diseases. Coronaviruses do not necessarily observe species barriers, as illustrated most graphically by the recent spread of three zoonotic viruses in humans, severe acute respiratory syndrome (SARS) coronavirus, Middle East respiratory syndrome (MERS) coronavirus and in 2019 SARS-CoV-2 responsible for the disease Covid-19 causing a global Pandemic infection. All of which appear to have originated from bats via an intermediate wild animal species before infecting humans, with lethal consequences. As a group, coronaviruses are not limited to particular organs; target tissues include the nervous system, immune system, kidney, and reproductive tract in addition to many parts of the respiratory and enteric systems. A great advance in recent years has been the development of systems ('infectious clones') for modifying the genomes of coronaviruses to study all aspects of coronavirus replication, and for the development of new vaccines.

Taxonomy and Classification

Coronaviruses are part of the Order *Nidovirales*, which is divided into five Suborders; the *Arnidovirineae*, which contains the Family *Arteriviridae*; the *Cornidovirineae*, which contains the Family *Coronaviridae*; the *Tornidovirineae*, which contains the Family *Tobamiviridae*; the *Mesonidovirineae*, which contains the Family *Mesonviridae*; and the *Ronidovirineae*, which contains the Family *Roniviridae*. The viruses generically known as coronaviruses fall within the *Coronaviridae* Family which are divided into four genera, the *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus* and *Deltacoronavirus*. Members of the *Nidovirales* Order have a similar genome organization and produce a nested set of subgenomic mRNAs and contain related specialized enzymes that are involved in replication of the RNA. Coronaviruses have been placed into different genera, initially on the basis of serological relationships which has subsequently been refined by gene sequencing.

Virion Properties

Virions have a buoyant density of approximately 1.18 g ml^{-1} in sucrose. Being enveloped viruses ([Fig. 1\(a\)](#)), they are destroyed by organic solvents such as ether and chloroform.

Virion Structure and Composition

All coronaviruses have four structural proteins in common ([Fig. 1\(b\)](#)): a large surface glycoprotein (S; c. 1150–1450 amino acids); a small envelope protein (E; c. 100 amino acids, present in very small amounts in virions); integral membrane glycoprotein (M; c. 250 amino acids); and a phosphorylated nucleocapsid protein (N; c. 500 amino acids). Some *Betacoronaviruses* have an additional structural glycoprotein, the hemagglutinin-esterase protein (HE; c. 425 amino acids). This is not essential for replication in vitro and may affect tropism in vivo.

Fig. 1 (a) Electron micrograph of an IBV virion, showing the bulbous S protein. (b) Diagrammatic representation of the composition and structure of a coronavirus virion: S, spike glycoprotein; M, M', integral membrane glycoprotein; E, small envelope protein; N, nucleocapsid protein; NC, nucleocapsid (nucleoprotein) comprising the RNA genome and N protein. Cryoelectron microscopy of TGEV has indicated a core structure comprising the NC and the M protein. Two forms of M protein (M, M') have been observed for TGEV (see main text). The coronavirus membrane proteins, S, E, M, and M', are inserted into a lipid bilayer (MEM) derived from internal cell membranes. (b) Reproduced from González, J.M., Gomez-Puertas, P., Cavanagh, D., Gorbalenya, A.E., Enjuanes, L., 2003. A comparative sequence analysis to revise the current taxonomy of the family. *Coronaviridae*. *Archives of Virology* 148, 2207–2235, with permission from Springer-Verlag.

Virions are *c.* 120 nm in diameter, although they can be up to twice that size, and the ring of S protein spikes is approximately 20 nm deep. When present, the HE protein forms a layer 5–10 nm deep. In some species, the S protein is cleaved into two subunits, the N-terminal S1 fragment being slightly smaller than the C-terminal S2 sequence. The S protein is anchored in the envelope by a transmembrane region near the C-terminus of S2. The functional S protein is highly glycosylated and exists as a trimer. The bulbous outer part of the mature S protein is formed largely by S1 while the stalk is formed largely by S2, having a coiled-coil structure. S1 is the most variable part of the S protein; some serotypes of the avian coronavirus, infectious bronchitis virus (IBV) differ from one another by 40% of S1 amino acids. S1 is the major inducer of protective immune responses. Variation in the S1 protein enables one strain of virus to avoid immunity induced by another strain of the same species.

The M glycoprotein is the most abundant protein in virions. In most cases, only a small part (~20 amino acids) at the N-terminus protrudes at the surface of the virus. There are three membrane-spanning segments and the C-terminal half of the M protein is within the lumen of the virus. In transmissible gastroenteritis virus (TGEV), a proportion of M molecules have four membrane-spanning segments, resulting in the C-terminus also being exposed on the outer surface of the virus (M' in Fig. 1(b)). The E protein is anchored in the membrane by a sequence near its N-terminus.

Fig. 2 Schematic diagram representing the genomic expression of the avian coronavirus IBV. The upper part of the diagram shows the IBV genomic RNA, with the various genes highlighted as boxed regions. The black boxes represent the transcription regulatory sequences (TRSs) found upstream of each gene and direct the synthesis, via negative-sense counterparts, of the sg mRNAs (2–6 for IBV). The leader sequence, represented by a gray box, is at the 5' end of the genomic RNA and at the 5' ends of the sg mRNAs. The genomic RNA is translated to produce two polyproteins, pp1a and pp1ab, that are cleaved by virus-encoded proteases to produce the replicase proteins. The structural proteins, S, E, M, and E, and the accessory proteins, 3a, 3b, 5a, and 5b, produced from IBV genes 3 and 5, respectively, are translated from the sg mRNAs. The proteins produced by the sg mRNAs are represented by lines below the corresponding sg mRNA. All of the sg mRNAs, except the smallest species, are polycistronic but only produce a protein from the 5'-most gene. The ribosome frameshift (RFS) region, denoted as a black circle on the genomic RNA, directs the -1 frameshift event for the synthesis of pp1ab. Translation of the genomic RNA results in the production of pp1a. However, the translating ribosomes undergo the -1 frameshift about 30% of the time resulting in pp1ab. The 5' and 3' UTR sequences are represented as single lines downstream of the leader and N gene sequences, respectively.

Genome Organization and Expression

Coronaviruses have the largest known RNA genomes, which comprise 28–32 kb of positive sense, single-stranded RNA. The overall genome organization being 5' UTR–polymerase gene–structural protein genes–3' UTR, where the UTRs are untranslated regions (Fig. 2). The first 60–90 nucleotides at the 5' end form a leader sequence. The structural protein genes are in the same order in all coronaviruses: (HE)–S–E–M–N. Interspersed among these genes are one or more other genes, often referred to as accessory genes as they have been demonstrated to be non-essential for replication in several coronaviruses using reverse genetic systems. The accessory genes encode small proteins of mainly unknown function. Some of these genes encode two or three proteins. In some cases (e.g., gene 3 of IBV and gene 5 of murine hepatitis virus (MHV)), translation of the third and second open reading frame (ORF), respectively, is affected by the preceding ORFs acting as internal ribosome entry sites. The proteins encoded by these small ORFs are mostly not required for replication *in vitro*; some of them might function as antagonists of innate immune responses.

Following entry into a cell and the release of the virus ribonucleoprotein (genome surrounded by the N protein) into the cytoplasm, ribosomes translate gene 1, which is approximately 20 kb, into two polyproteins (pp1a and pp1ab). These are cleaved by gene 1-encoded proteases, to generate 15 or 16 proteins (Fig. 3). Translation of gene 1 results in two polyproteins, translation of the ORF 1a region results in pp1a and translation of the ORF 1b region results in pp1ab, the latter involves ribosomal frameshifting, which has two elements, a slippery site followed by an RNA pseudoknot. At the slippery site (UUUAAAC in IBV), the ribosome slips one nucleotide backward and then moves forward, this time in a -1 frame compared with translation ORF 1a, resulting in the synthesis polyprotein 1ab, in which the proteins encoded by ORF 1b are in effect fused with the proteins from ORF 1a.

Proteins, including the RNA-dependent RNA polymerase (RdRp), from gene 1 associate to form the replicase complex, which is membrane associated. Coronavirus subgenomic mRNAs are generated by a discontinuous process. At the beginning of each gene is a common sequence (CUUAACAA in the case of IBV) called a transcription regulatory sequence (TRS). When the polymerase producing the nascent negative sense RNA, reaches a TRS, RNA synthesis is attenuated, followed by continuation at the 5' end of genomic RNA. This results in the addition of a negative copy of the leader sequence to the negative-sense RNA, resulting in a negative-sense copy of an sg mRNA. Of course, progress of the polymerase is not always halted at a TRS. Rather, it sometimes continues, producing a nested set of negative-sense sg mRNAs. These negative-sense copies of the sg mRNAs are the templates for the generation of the positive-sense sg mRNAs (Fig. 2). The amount of each sg mRNA does not necessarily decrease in a linear fashion; the efficiency of termination by a TRS is dependent on adjacent sequences, which are different for each gene. The leader sequence is found at the very 5' end of the genomic RNA and at the 5' ends of each sg mRNA.

Fig. 3 Organization of the coronavirus replicase gene products. Translation of the coronavirus replicase ORF 1a and ORF 1b sequences results in pp1a and pp1ab; the latter is a C-terminal extension of pp1a, following a programmed -1 frameshift event (see legend to Fig. 2). The two polyproteins are proteolytically cleaved into 10 (pp1a; nsp1–11) and 16 (pp1ab; nsp1–16) products by the papain-like proteinases (PL1^{pro} and PL2^{pro}) and the 3C-like (3CL^{pro}) proteinase. The PL^{pro} proteinases cleave at the sites indicated with a black triangle and the 3CL^{pro} proteinase cleaves at the sites indicated with a gray triangle. The nsp11 product of pp1a is produced as a result of the ribosomes terminating at the ORF 1a translational termination codon, a -1 frameshift results in the generation of nsp12, part of the pp1ab replicase gene product. Various domains have been identified within some of the replicase products: Ac is a conserved acidic domain; X = ADP-ribose 1'-phosphatase (ADRP) domain; PL1 and PL2 the two papain-like proteinases; Y is a conserved domain; TM1, TM2, and TM3 are conserved putative transmembrane domains; 3CL = 3CL^{pro} domain; RdRp, RNA-dependent RNA polymerase domain; HEL, helicase domain; ExoN, exonuclease domain; NendoU, uridylate-specific endoribonuclease domain; MT, 2'-O-ribose methyltransferase domain. nsp's 7–9 contain RNA-binding domains (RBDs).

Replication Cycle

The N-terminal (S1) part of the S protein mediates attachment to cells. It is a determinant of host species specificity and, in some cases, pathogenicity, by determining susceptible cell range (tissue tropism) within a host. The C-terminal S2 part triggers fusion of the virus envelope with cell membranes (plasma membrane or endosomal membranes), which can occur at neutral or slightly acidic pH, depending on species or even strain. The virus glycoproteins (S, M, and HE, when present) are synthesized at the endoplasmic reticulum. Both subunits of the S protein are multiply glycosylated, while the M protein has one or two glycans close to its N-terminus. Interestingly, glycosylation of the M protein can be either N- or O-linked, depending on the type of coronavirus, although experiments using reverse genetics showed that conversion of an O-linked glycosylated M protein to an N-linked version had no effect on virus growth.

Early and late in infection, formation of virus particles can occur in the endoplasmic reticulum–Golgi intermediate compartment (ERGIC) and endoplasmic reticulum, but most assembly occurs in the Golgi membranes. The M protein is not transported to the plasma membrane; its location at internal membranes determines the sites of virus particle formation. It interacts with the N protein (as part of the RNP) and C-terminal part of the S protein, retaining some, though not all, of the S protein at internal membranes. The E protein is essential for virus particle formation, though it is not known how it functions. It has a sequence that determines its accumulation at internal membranes, and its interaction with the M protein. The latter's interaction with the N protein enables the formation of virus particles with spikes.

Genome Replication and Recombination

Following infection of a susceptible cell, the coronavirus genomic RNA is released from the virion into the cytoplasm and immediately recognized as an mRNA for the translation of the replicase pp1a and pp1ab proteins. These proteins are cleaved by ORF1a-encoded proteases, after which they become part of replicase complexes for the synthesis of either complete negative-sense copies of the genomic RNA or negative-sense copies of the sg mRNAs. The negative-sense RNAs are used as templates for the synthesis of genomic RNA and sg mRNAs (Fig. 2). RNA synthesis appears to take place in replication complexes associated with rearranged host membranes generated by several pp1a derived proteins. Following synthesis of the sg mRNAs, the structural proteins are produced for the assembly and encapsidation of the *de novo*-synthesized genomic RNA, resulting in the release of new infectious coronavirus virions. The release of new virions starts 4–7 h after the initial infection. As indicated above, the synthesis of the sg mRNAs is the result of a discontinuous process in which the synthesis of a negative-sense copy of an sg mRNA is completed

by the addition of the negative-sense leader sequence by a recombination mechanism. If a cell is infected with two related coronaviruses, the polymerase may swap between two RNA templates, in a similar way to addition of the leader sequence. This 'copy-choice' mechanism of genetic recombination results in a chimeric RNA. Such RNAs may give rise to new viruses with modified genomes with a capacity to infect a different cell and, in some cases, new host species.

Diseases and Host Range

Probably all coronaviruses replicate in epithelial cells of the respiratory and/or enteric tracts, though not necessarily producing clinical damage at those sites. The avian coronavirus (a *Gammacoronavirus*), IBV, not only causes respiratory disease but can also damage gonads in both females and males, and causes serious kidney disease (dependent on the strain of virus, and to some extent on the breed of chicken). IBV is able to replicate at virtually every epithelial surface in the host. Some coronaviruses have their most profound effect in the alimentary tract (e.g., the porcine coronavirus transmissible gastroenteritis virus (TGEV) causes $\geq 90\%$ mortality in neonatal pigs). Human coronaviruses are known to be associated with enteric and respiratory diseases (e.g., diarrhea), in addition to respiratory disease. SARS-CoV was also associated with diarrhea in humans, in addition to serious lung disease. Other coronaviruses, for example, MHV and porcine HEV, spread to cells of the central nervous system, producing disease, for example, acute or chronic demyelination in the case of MHV.

Coronavirus replication and disease are not necessarily restricted to a single host species. Canine enteric CoV and feline CoV can replicate and cause disease in pigs; these two viruses have proteins with very high amino acid identity to those of porcine TGEV. Canine respiratory CoV has proteins, including the S protein (which is the attachment protein and a determinant of host range), with very high amino acid identity ($\geq 95\%$) to other group 2 viruses Hu CoV-OC43 and BCoV. This raises the possibility of co-infection in these hosts. There is evidence that pheasant CoV can infect chickens, and IBV infect teal (a duck), though without causing disease. The most dramatic demonstration that coronaviruses can have a wide host range was provided by SARS-CoV. This appears to have its origin in bats, was transferred to various other species (e.g., civet cat) that were captured for trade, and then caused lethal disease in humans. A similar zoonotic pathway has been hypothesized for the infection of humans by SARS-CoV-2, again with an origin in bats but via, as yet unknown, intermediary host or hosts, though generally accepted via a wild animal in a live animal market.

Persistent infections *in vivo* are well known for MHV, and less well known for other coronaviruses (e.g., IBV). Following infection of very young chickens, IBV is re-excreted when hens start to lay eggs. The trigger for release is probably the stress of coming into lay.

The S protein is a determinant of both tissue tropism within a host and host range. This has been elegantly demonstrated by genetic manipulation of the genome of MHV, which is unable to attach to feline cells. Replacement of the MHV S protein gene with that of CoV from feline coronavirus resulted in a recombinant virus that was able to attach, and subsequently replicate in, feline cells. However, other proteins can also affect pathogenicity. Research with genetically modified coronaviruses, using targeted recombination or 'infectious clones', has shown that modifications to proteins encoded in ORF1 and the small genes interspersed among the structural protein genes, result in attenuation of pathogenicity. Although the roles of these 'accessory proteins' are not known, this may offer a route to the development of a new generation of live vaccines. Currently, the most widely used prophylactics for control of IBV in chickens include killed vaccines and live vaccines attenuated by passage in embryonated eggs. However, disease control is complicated by extensive variation in the S1 protein which is the inducer of protective immunity.

Glossary

Cell tropism Process that determines which cells can be infected by a virus. Factors such as receptor express can influence the cell type that can be infected.

Discontinuous transcription Process by which the coronavirus leader sequence and body sequence are joined to generate subgenomic RNAs.

Double membrane vesicles (DMVs) Vesicles that are generated during coronavirus replication when viral replicase proteins sequester host cell membranes. These vesicles are the site of coronavirus RNA synthesis.

Transcriptional regulatory sequences (TRSs) Sequences that are recognized by the coronavirus transcription complex to generate leader-containing subgenomic RNAs.

Introduction

Coronaviruses (CoVs) were first identified during the 1960s by using electron microscopy to visualize the distinctive spike glycoprotein projections on the surface of enveloped virus particles. It was quickly recognized that CoV infections are quite common, and that they are responsible for seasonal or local epidemics of respiratory and gastrointestinal disease in a variety of animals. CoVs have been named according to the species from which they were isolated and the disease associated with the viral infection. Avian infectious bronchitis virus (IBV) infects chickens, causing respiratory infection, decreased egg production, and mortality in young birds. Bovine coronavirus (BCoV) causes respiratory and gastrointestinal disease in cattle. Porcine transmissible gastroenteritis virus (TGEV) and porcine epidemic diarrhea virus (PEDV) cause gastroenteritis in pigs. These CoV infections can be fatal in young animals. Feline infectious peritonitis virus (FIPV) and canine coronavirus (CCoV) can cause severe disease in cats and dogs. Depending on the strain of the virus and the site of infection, the murine CoV mouse hepatitis virus (MHV) can cause hepatitis or a demyelinating disease similar to multiple sclerosis. CoVs also infect humans. Human coronaviruses (HCoVs) 229e and OC43 are detected worldwide and are estimated to be responsible for 5–30% of common colds and mild gastroenteritis. Interestingly, HCoV-OC43 and BCoV share considerable sequence similarity, indicating a likely transmission across species (either from cows to humans or vice versa) and then adaptation of the virus to its host. In contrast to the relatively mild infections caused by HCoV-229e and HCoV-OC43, the CoV responsible for severe acute respiratory syndrome (SARS-CoV) causes atypical pneumonia with a 10% mortality rate. Two additional HCoVs, HCoV-NL63 and HCoV-HKU1, were identified using molecular methods and are associated with upper and lower respiratory tract infections in children, and elderly and immunosuppressed patients. Most recently, a coronavirus likely endemic in the camel population has been associated with Middle East Respiratory Syndrome (MERS) in humans. MERS-CoV can cause a lethal respiratory disease and renal syndrome, and mortality is highest in older individuals with co-morbidities such as diabetes or immunosuppression. CoVs are grouped according to sequence similarity as alpha-, beta, gamma or deltacoronaviruses (see www.viprbrc.org for a complete list of reference genomes for coronaviruses).

To date, the most infamous example of zoonotic transmission of a CoV is the outbreak of SARS in 2002–03. We now know that the outbreak started with cases of atypical pneumonia in the Guangdong Province in southern China in the fall of 2002. The infection was spread to tourists visiting Hong Kong in February, 2003, resulting in the dissemination of the outbreak to Hong Kong, Vietnam, Singapore, and Toronto, Canada. After attempting to treat cases of atypical pneumonia in Vietnam and acquiring the infection himself, Dr. Carlo Urbani alerted the World Health Organization (WHO) that this disease of unknown origin may be a threat to public health. The WHO rapidly organized an international effort to identify the cause of the outbreak, and within months a novel CoV was isolated from SARS patients and identified as the causative agent. Sequence analysis revealed that the virus was related to, but distinct from, all known CoVs. This led to an intensive search for an animal reservoir for this novel CoV. Initially, the masked palm civet and raccoon dog were implicated in the chain of transmission, since a SARS-CoV-like virus could be isolated from some animals found in wild animal markets in China. However, SARS-CoV-like viruses were never detected if these animals were captured from the wild, indicating that the civets may have only served as an intermediate host in the chain of transmission. Further investigation revealed that the likely reservoir for SARS-CoV is the Chinese horseshoe bat (*Rhinolophus* spp.), which is endemically infected with a virus, named bat-SARS-CoV, that is closely related to SARS-CoV (Fig. 1(a)). The bringing together of CoV-infected bats and susceptible civet cats and humans in live animal markets in China likely contributed to the emergence of SARS-CoV in 2002–2003.

In 2012, a novel coronavirus eventually termed Middle East Respiratory Syndrome Coronavirus (MERS-CoV) was isolated from a patient suffering from pneumonia in Saudi Arabia. MERS-CoV was then linked to multiple outbreaks of severe respiratory disease in the Middle East. Sequence analysis revealed that MERS-CoV was similar to but distinct from CoVs previously identified in bats in Europe and Asia. Further epidemiologic studies revealed that MERS-CoV could be isolated from the respiratory and

Fig. 1 Zoonotic transmission of emerging coronaviruses. (a) SARS-like coronaviruses are endemic in bats in Southern China. Virus transmission events may occur when animals are brought together in live animal markets. Replication of the virus in an intermediate host allows for the acquisition of adaptive mutations that allow for an expanded host range. SARS-CoV adapted to use the ACE-2 receptor in humans and can be spread by respiratory droplets. Infection with SARS-CoV generally results in symptomatic infection (red dots) characterized by fever and pneumonia. Super-spreader events (one person infecting many others) followed by global travel led to the pandemic of 2003. The quarantine of infected individuals and their contacts led to the cessation of the outbreak. (b) MERS-like viruses have been identified in bats and may be the progenitor of the virus now recognized to be endemic in camels in parts of the Middle East and Africa. MERS-CoV infection of camels seems to cause a respiratory disease with no significant mortality in young or adult camels. MERS-CoV infection in humans, proposed to be acquired from contact with camels or raw camel milk or meat, may cause pneumonia (red dot) or mild or asymptomatic illness (blue dot). Currently, there seems to be limited human-to-human transmission of MERS-CoV.

gastrointestinal tract of young camels and that the majority of adult camels tested had neutralizing antibodies to MERS-CoV, consistent with the idea that this virus was endemic in the camel population in the Middle East and in some regions of Africa. Currently, the majority of MERS-CoV infections are proposed to be acquired from either contact with camels or camel products such as raw milk or meat. There is some evidence supporting human to human transmission of MERS-CoV in hospital and home settings, however to date the virus has not evolved to be transmitted easily from human to human ([Fig. 1\(b\)](#)). Estimates of mortality from MERS-CoV are in the range of 30–40%, so there is significant concern about the pandemic potential of this emerging coronavirus should it evolve to transmit efficiently between humans. The existence of animal reservoirs for SARS-CoV and MERS-CoV presents the possibility for sporadic re-emergence of these significant human pathogens. By improving our understanding of the molecular aspects of CoV replication and pathogenesis, we may facilitate development of appropriate antiviral agents and vaccines to control and prevent diseases caused by known and potentially emerging CoVs.

Molecular Features of CoVs

CoV virions ([Fig. 2\(a\)](#)) are composed of a large RNA genome, which combines with the viral nucleocapsid protein (N) to form a helical nucleocapsid, and a host cell-derived lipid envelope which is studded with virus-specific proteins including the membrane (M) glycoprotein, the envelope (E) protein, and the spike (S) glycoprotein. CoV particles vary somewhat in size, but average about 100 nm in diameter. The genomic RNA (gRNA) inside the virion, which ranges in size from 27 to 32 kb for different CoVs, is the largest viral RNA identified to date. CoV gRNAs have a broadly conserved structure which is illustrated by the SARS-CoV genome shown in [Fig. 2\(b\)](#). The gRNA is capped at the 5' end, with a short leader sequence followed by two long open reading frames (ORFs) encoding the replicase polypeptide. The remaining part of the genome encodes the viral structural and so-called accessory proteins. The structural protein genes are always found in the order S–E–M–N, but accessory protein genes may be interspersed at various sites between the structural genes. SARS-CoV has the most complex genome yet identified, with eight ORFs encoding accessory proteins. The expression of these ORFs is not required for viral replication, but they may play a role in the pathogenesis of SARS and MERS. In addition, the products of accessory genes may be incorporated into the virus particle, potentially altering the tropism or enhancing infectivity. For SARS-CoV, the proteins encoded in ORFs 3a, 6, 7a, and 7b have been shown to be incorporated in virus particles, but the exact role of these proteins in enhancing virulence is not yet clear.

The features of CoV structural proteins are shown in [Fig. 3](#). For each structural protein, a schematic diagram of the predicted structure of the protein is shown on the left and a linear display of the features is shown on the right. The CoV spike glycoprotein is essential for attachment of the virus to the host cell receptor and fusion of the virus envelope with the host cell membrane. CoV spike glycoproteins assemble as trimers with a short cytoplasmic tail and hydrophobic transmembrane domain anchoring the protein into the membrane. The spike glycoprotein is divided into the S1 and S2 regions, which are sometimes cleaved into separate proteins by cellular proteases during the maturation and assembly of virus particles. S1 contains the receptor-binding domain (RBD) and has been shown to provide the specificity of attachment for CoV particles. The cellular receptors and corresponding RBDs in S1 have been identified for several CoVs. MHV binds to murine carcinoembryonic antigen-related cell adhesion molecules (mCEACAM1 and mCEACAM2); TGEV, FIPV, and HCoV-229e bind to species-specific versions of

Fig. 2 CoV virion and the genome of SARS-CoV. (a) Schematic diagram of a CoV virion with the minimal set of four structural proteins required for efficient assembly of the infectious virus particles: S, spike glycoprotein; M, membrane glycoprotein; E, envelope protein; and N, nucleocapsid phosphoprotein which encapsidates the positive-strand RNA genome. (b) Schematic diagram of the gRNA of SARS-CoV. Translation of the first two open reading frames (ORF1a and ORF1b) generates the replicase polyprotein. ORFs encoding viral structural and accessory (orange) ORFs are indicated at the 3' end of the genome. (a) Reprinted from Masters PS (2006) *The molecular biology of coronaviruses. aminopeptidase N. Interestingly, both HCoV-NL63 and SARS-CoV have been shown to bind to human angiotensin-converting enzyme 2 (ACE2). MERS-CoV binds to dipeptidyl peptidase (DPP4 or CD26). ACE2 and DPP4 are expressed in both the respiratory and gastrointestinal tracts, consistent with virus replication at both of these sites.

Once the S1 portion of the spike has engaged the host cell receptor, the protein undergoes a dramatic conformational change to promote fusion with the host cell membrane. Depending on the virus strain, this can occur at the plasma membrane on the surface of the cell, or in acidified endosomes after receptor-mediated endocytosis. The critical elements in the conformational change are the heptad repeats, HR1 and HR2, and the fusion peptide, F. After engaging the receptor, there is a dissociation of S1 which likely triggers the rearrangement of S2 so that HR1 and HR2 are brought together to form an antiparallel, six-helix bundle. This new conformation brings together the viral and host cell membranes and promotes the fusion of the lipid bilayers and introduction of the nucleocapsid into the cytoplasm. During infection, the spike glycoprotein is also present on the surface of the infected cell where it may (depending on the virus strain) promote fusion with neighboring cells and syncytia formation. The spike glycoprotein is also the major antigen to which neutralizing antibodies develop. The spike protein is a target for development of therapeutics for treatment of CoV infections. Monoclonal antibodies directed against the spike neutralize the virus by blocking binding to the receptor; synthetic peptides that block HR1-HR2 bundle formation have also been shown to block CoV infection.

The membrane (M) and envelope (E) proteins are essential for the efficient assembly of CoV particles. M is a triple-membrane-spanning protein that is the most abundant viral structural protein in the CoV virion. The ectodomain of M is generally glycosylated, and is followed by three transmembrane domains and an endodomain which is important for interaction with the nucleocapsid protein and packaging of the viral genome. The E protein is present in low copy numbers in the virion, but is important for efficient assembly. In the absence of E protein, few or no infectious virus particles are produced. The exact role of the E protein in the assembly of virus particles is still unknown, but recent studies suggest that E may act as an ion channel. The nucleocapsid protein (N) is an RNA-binding protein and associates with the CoV gRNA to assemble ribonucleoprotein complexes. The N protein is phosphorylated, predominantly at serine residues, but the role of phosphorylation is currently unknown. The N protein has three conserved domains, each separated by highly variable spacer elements. Domains 1 and 2 are rich in arginine and lysine residues, which is typical of many RNA-binding proteins. Domain 3 is essential for interaction with the M protein and assembly of infectious virus particles. The N protein has been shown to be an important cofactor in CoV RNA synthesis and is proposed to act as an RNA chaperone to promote template switching, as described below.

Fig. 3 Diagrammatic representation of the spike trimer assembled on membranes, with the S1 receptor binding domain (RBD) and S2 fusion domain indicated. The linear map of spike indicates the location of the RBDs for three CoVs, and the relative location of the heptad repeat domains 1 and 2 (HR1 and HR2) which mediate the conformational changes required to present the fusion peptide (F) to cellular membranes. The membrane (M), envelope (E), and nucleocapsid (N) proteins represented in association with membranes or viral RNA. The linear map of each protein highlights the transmembrane domains of M and E and the RNA-binding and M protein-binding domains of N. Domains 1 and 2 of N are rich in arginine and lysine (indicated by +). Replication and Transcription of CoV RNA

The replication and transcription of CoV RNA takes place in the cytoplasm of infected cells (Fig. 4). The CoV virion attaches to the host cell receptor via the spike glycoprotein and, depending on the virus strain, the spike mediates fusion directly with the plasma membrane or the virus undergoes receptor-mediated endocytosis and spike-mediated fusion with endosomal membranes to release the viral gRNA into the cytoplasm. Once the positive-strand RNA genome is released, it acts as a messenger RNA (mRNA) and the 5' end (ORF1a and ORF1b) is translated by ribosomes to generate the viral RNA-dependent RNA polymerase polypeptide, termed the viral replicase. Translation of ORF1b is dependent on ribosomal frameshifting, which is facilitated by a slippery sequence and RNA pseudoknot structure present in all CoV gRNAs. The replicase polypeptide is processed by replicase-encoded proteases (papain-like proteases and a poliovirus 3C-like protease) to generate 16 mature replicase products. These viral replicase proteins sequester host cell membranes to generate distinctive double-membrane vesicles (DMVs) that have been shown to be the site of CoV RNA synthesis. The replicase complex on the DMVs then mediates the replication of the positive-strand RNA genome to generate full-length and subgenomic negative-strand RNAs, and the subsequent production of positive-strand gRNAs and sgmRNAs. The sgmRNAs are translated to generate viral structural and accessory proteins, and virus particles assemble with positive-strand gRNA in the endoplasmic reticulum-Golgi intermediate compartment (ERGIC) and bud into vesicles, with

Fig. 4 Replication cycle of CoVs. The spike glycoprotein on the virus particle interacts with host cell receptors to mediate fusion of the virus and host cell membranes and release of the positive-strand RNA genome into the cytoplasm. The 5'-proximal open reading frames (ORF1a and ORF1b) are translated from the gRNA to generate the replicase polyprotein. The replicase polyprotein is processed by viral proteases into 16 nonstructural proteins which assemble with membranes to generate double-membrane vesicles (DMVs) where RNA synthesis takes place. A nested set of 3' co-terminal subgenomic (sg) RNAs is generated by a discontinuous transcription process. The sgRNAs are translated to generate the viral structural and accessory proteins. Viral gRNA is replicated and associates with nucleocapsid protein and viral structural proteins in the endoplasmic reticulum-Golgi intermediate compartment (ERGIC), where virus particles bud into vesicles before transport and release from the cell. Reprinted from Masters PS (2006) *The molecular biology of coronaviruses. Advances in Virus Research* 66: 193–292, with permission from Elsevier.

subsequent release from the cell. Depending on the virus strain, this replication can be robust and result in destruction of the host cell or a low-level, persistent infection that can be maintained in cultured cells or infected animals.

A hallmark of CoV transcription is the generation of a nested set of mRNAs, with each mRNA having the identical 'leader' sequence of approximately 65–90 nt at the 5' end (Fig. 5(a)). The leader sequence is encoded only once at the 5' end of the gRNA. Each subgenomic mRNA (sgmRNA) has the identical leader sequence fused to the 5' end of the body sequence. How are the leader-containing mRNAs generated during CoV transcription? Current evidence supports a model of discontinuous transcription, whereby the replicase complex switches templates during the synthesis of negative-strand RNA (Fig. 5(b)). The key sequence element in this process is the transcriptional regulatory sequence (TRS). The TRS is a sequence of approximately 6–9 nt (5'-ACGAAC-3' for SARS-CoV) which is found at the end of the leader sequence and at each intergenic region (the sites between the open reading frames encoding the viral structural and accessory proteins). Site-directed mutagenesis and deletion analysis has revealed the critical role of the TRS in mediating transcription of sgmRNAs. Deletion of any intergenic TRS results in loss of production of the corresponding sgmRNA. In addition, the CoV leader TRS and the intergenic TRS sequences must be identical for optimal production of the sgmRNAs. A three-step working model for template switching during negative-strand RNA synthesis has been proposed to describe the process for the generation of CoV leader-containing sgmRNAs (Fig. 5(b)). In this process, the 5' end and 3' end of the gRNA form a complex with host cell factors and the viral replication complex. The 3' end of the positive strand is used as the template for the initiation of transcription of negative-strand RNA. Negative-strand RNA synthesis continues up to the point of the TRS. At each TRS, the viral replicase may either read through the sequence to generate a longer template, or switch templates to copy the leader sequence. The template switch allows the generation of a leader-containing sgmRNA. In this model, alignment of the leader TRS, the newly synthesized negative-strand RNA, and the genomic TRS is critical for the template switching to occur. Disruption of the complex, or loss of base-pairing within the complex, will result in the loss of production of that

Fig. 5 Model of SARS-CoV gRNA and sgRNAs, and a working model of discontinuous transcription. (a) Diagram of gRNA and the nested set of sgRNAs of SARS-CoV. The 5' leader sequence, the transcriptional regulatory sequences (TRSs), and the positive- and negative-sense sgRNAs are indicated. (b) A working model of CoV discontinuous transcription. I. 5'-3' complex formation. Binding of viral and cellular proteins to the 5' and 3' ends of the CoV gRNA is represented by ellipsoids. The leader sequence is indicated in red, the TRS sites are in orange. II. Base-pair scanning step. Minus-strand RNA (light blue) is synthesized from the positive-strand template by the viral transcription complex (hexagon). At the TRS site, base-pairing may occur between the template, the nascent negative-strand RNA, and the leader TRS sequence (dotted lines). III. The synthesis of negative-strand RNA can continue to make a longer sgRNA III, or a template switch can take place III' to generate a leader-containing subgenomic negative-strand RNA, which could then serve as the template for leader-containing positive-strand sgRNAs. Modified from Enjuanes L, Almazán F, Sola I, and Zunia S (2006) Biochemical aspects of coronavirus replication: A virus–host interaction. *Annual Reviews in Microbiology* 60: 211–230.

sgmRNA. Further studies of the CoV replication complex may yield new insights into the role of the viral helicase and endoribonuclease in the generation of the leader-containing CoV RNAs.

Another hallmark of CoV replication is high-frequency RNA recombination. RNA recombination occurs when a partially synthesized viral RNA dissociates from one template and hybridizes to similar sequences present in a second template. Viral RNA synthesis continues and generates a progeny virus with sequences from two different parental genomes. This RNA recombination event is termed copy-choice recombination. Copy-choice RNA recombination can be demonstrated experimentally when two closely related CoV strains (such as MHV-JHM and MHV-A59) are used to coinfect cells. Recombinant viruses with cross-over sites throughout the genome can be isolated, although sequences within the spike glycoprotein may be a 'hot spot' for recombination due to the presence of RNA secondary structures that may promote dissociation and reassociation of RNA. It has been proposed that copy-choice recombination is also the mechanism by which many CoVs have acquired accessory genes, and it has been exploited experimentally for the deletion or insertion of specific sequences in CoV genomes to assess their role in virus replication and pathogenesis.

CoV Accessory Proteins

Sequence analysis of CoVs isolated from species ranging from birds to humans has revealed that all CoVs encode a core canonical set of genes, replicase (rep), spike (S), envelope (E), membrane (M), and nucleocapsid (N), and additional, so-called accessory genes (Table 1). The canonical genes are always found in the same order in the genome: rep-S-E-M-N. Reverse genetic studies (see below) have shown that this is the minimal set of genes required for efficient replication and assembly of infectious CoV particles. However, the genomes of all CoVs sequenced to date encode from one to eight additional ORFs, which code for accessory proteins. As the name implies, these accessory proteins are not required for CoV replication in tissue culture cell lines, but they may play important roles in tropism and pathogenesis *in vivo*. How were these additional genes acquired? Current evidence indicates that these additional sequences may have been acquired by RNA recombination events between co-infecting viruses. For example, the hemagglutinin-esterase (HE) glycoprotein present in four different CoVs (MHV, BCoV, HCoV-OC43, and HCoV-HKU-1) was

likely acquired by recombination of an ancestral CoV with the HE glycoprotein gene of influenza C. Interestingly, the expression of the HE gene has no effect on replication of the virus in cultured cell lines, but has been shown to enhance virulence in infected animals. Other CoV accessory genes may have been acquired through recombination with host cell mRNA or other viral mRNAs. The specific role of the accessory proteins in CoV replication and pathogenesis is under investigation. For SARS-CoV, accessory protein 6 has been implicated as an important factor in viral pathogenesis. Researchers have shown that mice infected with murine CoV expressing SARS-CoV protein 6 rapidly succumb to the infection, indicating that the protein 6 enhances virulence. In addition, studies suggest that SARS-CoV accessory proteins may play a role in blocking host cell innate immune responses, which may enhance viral replication and virulence. Other accessory proteins, such as SARS-CoV 3a and 7a, have been shown to be packaged into virus particles, where they may enhance infectivity or alter cell tropism. Future studies will be aimed at elucidating how CoV accessory proteins modulate the innate immune response to coronavirus replication.

Manipulating CoV Genomes Using RNA Recombination and Reverse Genetics

Genetic manipulation of CoV sequences is challenging because of the large size (27–32 kbp) of the RNA genomes. However, two approaches have been developed to allow researchers to introduce mutations, deletions, and reporter genes into CoV genomes. These approaches are (1) targeted RNA recombination and (2) reverse genetics using infectious cDNA constructs of CoV. The first approach exploits high-frequency copy-choice recombination to introduce mutations of interest into the 3' end of the CoV gRNA. In the first step of targeted RNA recombination, a cDNA clone encoding the region from the spike glycoprotein to the 3' end of the RNA is generated. These sequences can be easily manipulated in the laboratory to introduce mutations or deletions, or for the insertion of reporter or accessory genes, into the plasmid DNA. Next, RNA is transcribed from the plasmid DNA and the RNA is transfected into cells coinfecting with the CoV of interest. RNA recombination occurs between the replicating CoV and the transfected substrate RNA, and viruses with the 3' end sequences derived from the transfected substrate RNA will be generated. The recombinant viruses are generated by high-frequency copy-choice recombination, but the challenge is to sort or select for the recombinant virus of interest from the background of wild-type virus. To facilitate selection of recombinant viruses, Masters and Rottier introduced the idea of host range-based selection. They devised a clever plan to use a mouse hepatitis virus (MHV) that encodes the spike glycoprotein from a feline CoV as the target for their recombination experiments. This feline-MHV, termed fMHV, will infect only feline cell lines. Substrate RNAs that encode the MHV spike and mutations of interest in the 3' region of the genome can be transfected into feline cells infected with fMHV, and progeny virus can be collected from the supernatant and subsequently selected for the ability to infect murine cell lines. Recombinant CoVs that have incorporated the MHV spike gene sequence (and the downstream substrate RNA with mutations of interest) can be selected for growth on murine cells, thus allowing for the rapid isolation of the recombinant virus of interest. This host range-based selection step is now widely used by virologists to generate recombinant viruses with specific alterations in the 3' end of the CoV genome.

The second approach for manipulating CoV sequences, generating infectious cDNA constructs of CoV, has been developed in several laboratories. Full-length CoV sequences have been cloned and expressed using bacterial artificial chromosomes (BACs), vaccinia virus vectors, and from an assembled set of cDNA clones representing the entire CoV genome. The generation of a full-length cDNA and subsequent generation of a full-length CoV gRNA allows for reverse genetic analysis of CoV sequences. Successful reverse genetics systems are now in place to study the replication and pathogenesis of SARS-CoV, MERS-CoV, MHV, HCoV-229e, and IBV. These reverse genetics systems have allowed researchers to introduce mutations into the replicase gene and identify sites that are critical for enzymatic activities of many replicase products such as the helicase, endoribonuclease, and the papain-like proteases. Reverse genetic approaches are also being used to investigate the role of the TRSs in controlling the synthesis of CoV mRNAs. Interestingly, the SARS-CoV genome can be 're-wired' using a novel, noncanonical TRS sequence, which must be present at both the ends of the leader sequence and at each intergenic junction. This 're-wired' SARS-CoV may be useful for generating a live-attenuated SARS-CoV vaccine. An important feature of this 're-wired' virus is that it would be nonviable if it recombined with wild-type virus, since the leader TRS and downstream TRS would no longer match in a recombinant virus. The development of reverse genetics systems for CoVs has opened the door to investigate how replicase gene products function in the complex mechanism of CoV discontinuous transcription, and provides new opportunities to generate novel CoVs as potential live-attenuated or killed virus vaccines to reduce or prevent CoV infections in humans and animals.

Vaccines and Antiviral Drug Development

Because of the economic importance of CoV infection to livestock and domestic animals, a variety of live-attenuated and killed CoV vaccines have been tested in animals. Vaccines have been developed against IBV, TGEV, CCoV, and FIPV. However, these vaccines do not seem to provide complete protection from wild-type virus infection. In some cases, the wild-type CoV rapidly evolves to escape neutralization by vaccine-induced antibodies. In studies of vaccinated chickens, a live-attenuated IBV vaccine has been shown to undergo RNA recombination with wild-type virus to generate vaccine escape mutants. Killed virus vaccines may also be problematic for some CoV infections. Vaccination of cats with a killed FIPV vaccine has been shown to exacerbate disease when cats are challenged with wild-type virus. Therefore, extensive studies will be required to carefully evaluate candidate vaccines for SARS-CoV or MERS-CoV. A variety of approaches are currently under investigation for developing CoV vaccines, including analysis of killed virus vaccines, live-attenuated virus vaccines, and viral vector vaccines (such as modified vaccine virus Ankara, canarypox, alphavirus, and adenovirus vectors). Studies have shown that removing the envelope (E) protein from either SARS-CoV or MERS-CoV is an effective approach for generating a live attenuated virus vaccine. In the absence of this structural protein, the virus replicates to lower titers in the lungs of mice, but still induces an immune response that is protective from challenge with wild type virus. The development of improved animal models for human coronaviruses will be essential for evaluating any candidate vaccines. Transgenic mice expressing human ACE-2 (for SARS-CoV) can be used as a model system for SARS, however the pathogenesis in ACE-2 expressing transgenic mice does not fully mimic the pathogenesis seen during SARS-CoV infection in humans. CoVs can be adapted for replication in small animal models. Passaging SARS-CoV in mice led to the generation of a mouse-adapted strain, SARS CoV-MA15, which induces a lethal respiratory tract infection of mice. CoV vaccine studies will benefit from an improved understanding of conserved viral epitopes that can be targeted for vaccine development.

The use of neutralizing monoclonal antibodies directed against the SARS-CoV or MERS-CoV spike glycoprotein is another approach that may provide protection from severe disease. The success in the development and use of humanized monoclonal antibodies against respiratory syncytial virus (family *Paramyxoviridae*) to protect infants from severe disease indicates that this approach is certainly worth investigating. Studies have shown that patient convalescent serum and monoclonal antibodies directed against the SARS-CoV spike glycoprotein efficiently neutralize infectious virus. Further studies are essential to evaluate any concerns about potential antibody-mediated enhancement of disease and to determine if neutralization escape mutants arise rapidly after challenge with infectious virus. Studies evaluating monoclonal antibodies directed against a variety of structural proteins, and monoclonal antibodies directed against conserved sites in the spike glycoprotein will provide important information on the efficacy of passive immunity to protect against emerging coronaviruses.

Currently, there are no antiviral drugs approved for use against any human CoV infection. With the potential for the emergence or re-emergence of pathogenic CoV from animal reservoirs, there is considerable interest in identifying potential therapeutic targets and developing antiviral drugs that will block viral replication and reduce the severity of CoV infections in humans. Two promising targets for antiviral drug development are the SARS-CoV protease domains, the papain-like protease (PL^{Pro}) and the 3C-like protease (3CL^{Pro}, also termed the main protease, M^{Pro}) (Fig. 6). These two protease domains are encoded within the replicase polyprotein gene and protease activity is required to generate the 16 replicase nonstructural proteins (nsp1–nsp16) that assemble to generate the viral replication complex. The crystal structure of the 3CL^{Pro} was determined first from TGEV and then from SARS-CoV. Rational drug design, much of which was based on our knowledge of inhibitors directed against the rhinovirus 3C protease, has provided promising lead compounds for 3CL^{Pro} antiviral drug development. Interestingly, these candidate antivirals have been shown to inhibit the replication of SARS-CoV and other group 2 CoVs such as MHV, and the less related group 1 CoV, HCoV-229e. This indicates that the active site of 3CL^{Pro} is highly conserved among CoVs and that antiviral drugs developed against SARS-CoV 3CL^{Pro} may also be useful for inhibiting the replication of more common human CoVs such as HCoV-229e, HCoV-OC43, HCoV-NL63, and HCoV-HKU1. Further studies are needed to determine if these inhibitors can be developed into clinically useful antiviral agents.

Fig. 6 CoV proteases are targets for antiviral drug development; X-ray structures of the two SARS-CoV protease domains encoded in the replicase polyprotein. (a) The SARS-CoV papain-like protease (PL^{pro}) with catalytic triad cysteine, histidine, and aspartic acid residues, and zinc-binding domain indicated. (b) The 3C-like protease (3CL^{pro}, also termed main protease, M^{pro}) dimer with catalytic cysteine and histidine residues indicated.

Analysis of SARS-CoV papain-like protease led to the surprising discovery that this protease is also a viral deubiquitinating (DUB) enzyme. The SARS-CoV PL^{pro} was shown to be required for processing the amino-terminal end of the replicase polyprotein and to recognize conserved cleavage site (-LXGG). The LXGG cleavage site is also the site recognized by cellular DUBs to remove poly-ubiquitin chains from proteins targeted for degradation by proteasomes. Analysis of the X-ray structure of the SARS-CoV PL^{pro} has revealed that it has structural similarity to known cellular DUBs. These studies suggest that CoV papain-like proteases have evolved to have both proteolytic processing and DUB activity. The DUB activity may be important in preventing ubiquitin-mediated degradation of viral proteins, or the DUB activity may be important in subverting host cell pathways to enhance viral replication. PL^{pro} inhibitors are now being developed using structural information and by performing high-throughput screening of small molecule libraries to identify lead compounds. The recent development of a chimeric virus system which uses Sindbis virus to express the SARS-CoV or MERS-CoV papain-like protease, facilitates the study of protease activity and the efficacy of protease inhibitors. The chimeric virus system can be used in a biosafety level 2 environment, compared to the biosafety level 3 containment required for the study of SARS-CoV or MERS-CoV. Additional CoV replicase proteins, particularly the RNA-dependent RNA polymerase, helicase, and endoribonuclease, are also being targeted for antiviral drug development.

Future Perspectives

The development of targeted RNA recombination and reverse genetics systems for CoVs has provided new opportunities to address important questions concerning the mechanisms of CoV replication and virulence, and to design novel CoV vaccines. In the future, improved small animal models for testing vaccines and antivirals, and the availability of additional X-ray crystallographic structure information for rational drug design will be critical for further progress toward development of effective vaccines and antiviral drugs that can prevent or reduce diseases caused by CoVs.

This is an update of C.A. Whitehouse, Crimean–Congo Hemorrhagic Fever Virus and Other Nairoviruses, in Encyclopedia of Virology (Third Edition), Edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00620-8.

Introduction

CCHFV is a tick-borne viral zoonosis found in Africa, Asia, eastern Europe and the Balkans. The geographic distribution of the virus correlates with that of ticks belonging to the genus *Hyalomma*, which are considered to be the principal vectors of the virus. Crimean-Congo hemorrhagic fever orthonairovirus (CCHFV) is a member of the *Orthonairovirus* genus of the family *Nairoviridae* within the *Bunyavirales* order of viruses. Species within the genus were grouped originally on the basis of antigenic relationships and morphological and genetic similarities. Recent taxonomic changes based on genomic characterizations, resulted in renaming of seven species within the genus and the addition of five new species to the genus. Taxonomic changes included revising the grouping of Hazara virus, historically considered to be the closest relative to CCHFV, and now placed in a separate species with Tofla virus. Neither of these viruses, Hazara and Tofla, are known to cause disease. Within the genus, CCHFV, the etiologic agent of mild to severe disease with fatalities, is considered to be the most significant public health concern. Nairobi sheep disease virus (NSDV), an important veterinary pathogen, causes severe disease in domestic sheep and goats in Africa and Ganjam virus, considered an isolate of NSDV, circulates in the Indian subcontinent. Lesser known human pathogenic orthonairoviruses include Dugbe virus and Kasokera virus, associated with febrile illness in Africa; Erve virus proposed to be the cause of thunderclap headache in Europe; and Issyk-Kul virus associated with febrile disease in central Asia. The remaining viruses within the *Orthonairovirus* genus have mostly been isolated from ticks, and the medical and/or veterinary significance of them is unknown.

A hemorrhagic disease with symptoms suggestive of CCHF infection was described in eastern Europe and Asia as far back as the 12th century. The disease given the name Crimean hemorrhagic fever (CHF) was first reported in an outbreak involving 200 soldiers and peasants on the Crimean peninsula in 1944. The following year the disease was shown to be caused by a filterable agent, but was only isolated in mice in 1967. In 1956 a virus was isolated from blood samples collected from a febrile child in Stanleyville in the Belgian Congo (now referred to as Kisangani in the Democratic Republic of the Congo) and given the name Congo virus. The availability of a laboratory host made it possible to further characterise the two viruses and in 1969 it was reported that the virus from Europe and Asian Republics of USSR and Bulgaria were antigenically identical to Congo virus from Africa. The names were combined and the virus is now referred to as Crimean-Congo hemorrhagic fever virus.

Due to the high fatality rate, the propensity to cause nosocomial infections and a lack of specific anti-viral treatment or vaccine, the virus is classified among biosafety level 4 pathogens. This dictates that the virus can only be handled and cultured within the confines of a maximum containment facility. This requirement for a biosafety level 4 laboratory limits the number of facilities that culture the virus and has likely contributed to our incomplete understanding on the pathogenesis of disease and the correlates of protection. Development of vaccines was initially thwarted by the lack of suitable animal models however the identification of murine models, and more recently a non-human primate model, has contributed to recent development of candidate vaccines.

The emergence and re-emergence of CCHFV in Balkan countries and south western regions of the Russian Federation, and more recently in southern regions of Europe, highlights the potential for this pathogen to spread to non-endemic regions where ticks of the *Hyalomma* genus are present.

Virion Structure, Genome and Life Cycle

The CCHF virion is spherical and approximately 80–100 nm in diameter with a bilayered lipid envelope. The viral glycoproteins G_N and G_C protruding from the lipid envelop are likely associated with receptor recognition and are involved in the early steps of viral replication. The CCHFV contain the negative-sense small (S), medium (M) and large (L) genome segments, encapsidated by the nucleoprotein (N), and the RNA dependent RNA polymerase (RdRp), which are responsible to initiate transcription and genome replication in the host cell. The terminal complementary sequences 5'-UCUCAAGA and 3'-AGAGUUUCU are conserved in all nairoviridae members.

The S Segment

The S segment encodes the N, which is the most abundant viral protein in the CCHFV particles, playing a key role in the encapsidation of viral genomic. The CCHFV N structure organize a large globular domain, to which N- and C-terminal portions of the polypeptide

Fig. 1 CCHF virus genome. CCHF virus consist of tri-segmented negative sense RNA genome. The small (~1.6 kb), medium (~5.4 kb) and large (~12.1 kb) segments, code for the N, the GPC and the L protein, respectively. The small segment also codes for a non-structural S protein (NSS) in opposite sense. The coding regions are flanked by non-coding regions (NCRs).

contribute, plus a protruding “arm” containing a conserved caspase-3 cleavage site on the top of the arm. Most probably the globular region is responsible for RNA binding. The S segment can also codes for a non-structural protein in ambisense direction (**Fig. 1**).

The M Segment

The M segment encodes a single polyprotein, the glycoprotein precursor (GPC) (**Fig. 1**). The maturation of CCHFV GPC is very complex and does not share much similarity with glycoprotein processing in other bunyaviruses. GPC maturation yields to two type I transmembrane glycoproteins, G_N and G_C which are spiked on the virus envelope. The GPC processing in the endoplasmic reticulum (ER) and Golgi results in two structural glycoproteins, G_N and G_C , and nonstructural proteins designated GP160, GP85, and GP38 [and the non-structural M protein (NSM). The GPC is heavily glycosylated and subsequently cleaved by host proteases including the proprotein convertases.

The L Segment

Nairoviridae have an unusually large RNA dependent RNA polymerase protein (nearly twice the size) compared to those of other members (**Fig. 1**). This segment has a single open reading frame, and encodes an approximately 4000-amino acid polyprotein. The

amino acids 1–609 contain domains with the ovarian tumor (OTU) cysteine protease function. Sequences located between the OTU domain and the RdRp conserved motifs contain a potential leucine zipper and a C2H2 zinc finger motif.

Virus Life Cycle

The CCHFV GN and/or GC are involved in early step of replication cycle of CCHFV. It has been suggested that GC is responsible for binding to the cellular receptors and mediates fusion in endosomes (Fig. 2). The processes of internalization, virion assembly

Fig. 2 CCHFV replication cycle. CCHFV binds to an unknown cellular receptor and penetrate into the cells in a clathrin-dependent manner. After fusion, the viral genome is released to the cytoplasm. The viral mRNAs are translated into the NP and L proteins at cytoplasm, and the glycoprotein precursor (GPC) translated into endoplasmic reticulum (ER). The NP and L protein helping to replicate the genomic RNA. The GPC is processed and matured to Gn and Gc in the ER and the Golgi. The new CCHFV particles most probably assemble in the Golgi followed by virus release in Golgi-derived vesicles. The figure illustrated by Dr. J Vermeulen.

and egress are dependent on host-cell skeleton. The cellular receptors for CCHFV entry have not been identified. A functional interaction has been suggested between CCHFV GC and cell surface nucleolin. Following adsorption of CCHFV at plasma membrane, the CCHFV is endocytosed through a clathrin-mediated endocytosis mechanism. CCHFV entry has also been suggested to be dependent on cholesterol and a low pH. Following endocytosis, CCHFV particles are transported to early endosomes and subsequently to multivesicular bodies (MVB), where the CCHFV membrane is fused to the endosomes membrane. Following this process the genomic RNPs are released into the cytosol and transcription and replication process will be initiated. The replication of the RNPs minimally require the L protein and N. Since CCHFV is a negative strand RNA virus, genomic RNPs are used as template to synthesize capped mRNA. These process are followed by transcription and viral protein processing and subsequent maturation. The assembly and egress process for CCHFV is most probably like other bunyaviruses.

Epidemiology

CCHF is the most geographically extensive viral hemorrhagic fever and the most widespread medically significant tick-borne viral disease. It is estimated that 3 billion people in Africa, Asia and Europe are at risk, and 10,000–15,000 infections and 500 fatalities occur annually. Ticks of the *Hyalomma* genus (mainly *H. marginatum*, *H. rufipes*, *H. anatolicum*, and *H. asiaticum*) are the principal competent vectors and reservoirs of CCHFV. The occurrence of the disease coincides with the geographic distribution of *Hyalomma* spp. ticks, with a 50° north latitude limit, which, however, is predicted to increase to northern areas due to warming climate. Although CCHFV has been detected or isolated from ticks in several other genera, their role in CCHF epidemiology remains unclear.

CCHFV circulates unnoticed in nature between ixodid ticks and vertebrate hosts. The virus is maintained in ticks transovarially, transovarially, venereally and by co-feeding on infected or uninfected animals. Ticks remain persistently infected. The immature *Hyalomma* spp. ticks (larvae and nymphs) feed mainly on ground-feeding birds and small mammals and remain attached for up to 26 days. Adult ticks actively seek larger mammals, including hares, wild and domesticated ungulates, or humans. Overwintering infected ticks maintain the virus in nature. Transmission to humans occurs by bite or crushing of an infected tick or by direct contact (percutaneous and permucosal) with blood or tissues from viremic patients or livestock. Therefore, groups at higher risk are agricultural and abattoir workers, individuals involved in backyard slaughtering in endemic areas and health-care personnel. Nosocomial infections have been reported when exposure to the virus was substantial; the risk is higher when the patient presents hemorrhagic manifestations. Isolation of the patient and barrier nursing should be applied. Epidemiological and behavioral factors that play a role in acquisition of the CCHFV infection differ among countries; e.g., while tick bite is the main mode of transmission in Turkey, the contact with the blood of infected livestock, seems to be the main route of CCHFV transmission to humans in Iran.

Cases are seen from spring to autumn and they are usually sporadic. Non-nosocomial epidemics or outbreaks occur when environmental (e.g., mild winters, dry summers) and anthropogenic conditions (e.g., land fragmentation, socioeconomic changes) result in high tick populations leading to increased human exposure to ticks. Several biotic and abiotic drivers contribute to shape a favorable ecosystem. Given that CCHFV can be spread in long distances by migratory birds infested with infected ticks, or transported through international livestock trade, virus introduction in a suitable new habitat can lead to disease emergence and establishment. This was seen in Turkey, India and Spain where the disease emerged in 2002, 2011 and 2016, respectively. Based on environmental suitability, predictive risk maps have been constructed which can direct surveillance studies.

The epidemiology of CCHF is changing, as the disease emerged in new places, while the incidence differs between years. Currently, the most CCHF-affected country is Turkey; since 2002, when CCHF emerged in the country, more than 10,000 cases have been registered, with the majority of them being observed in 2008 and 2009 (more than 1000 cases annually). The most endemic areas are in the Middle Anatolia-Black Sea region. Sporadic CCHF human cases and outbreaks have been reported in more than 30 countries in three continents. In Asia, CCHF has been reported from Afghanistan, China, India, Iran, Iraq, Kazakhstan, Kuwait, Oman, Pakistan, Saudi Arabia, Tajikistan, Turkey, Turkmenistan, United Arab Emirates, and Uzbekistan. In Europe, CCHF has been reported in Albania, Bulgaria, Georgia, Kosovo, Russia, Ukraine and Spain, while one single case has been reported in Greece. Among African countries, CCHF has been reported in Burkina Faso, Democratic Republic of Congo, Egypt, Kenya, Mauritania, Nigeria, Senegal, Somalia, Republic of South Africa, Namibia, Sudan, Tanzania and Uganda. Furthermore, detection of the virus in ticks or detection of viral antibodies in humans and/or livestock, in the absence of clinical case, has been reported in several countries. Wild and domestic animals infected with CCHFV develop only a transient viremia without presenting symptoms of the disease. Seroprevalence studies in humans, livestock and wild animals enable the identification of CCHFV endemic foci.

CCHFV presents the most extensive genetic diversity among arboviruses. The highest level of diversity is seen in the M RNA segment, and especially in the mucin-like region. This phenomenon can be explained by the fact that the virus has to adapt to a variety of host (tick and vertebrate) cells, prompting for genetic changes and complex virus evolution. Based on S RNA segment sequences, seven genetic clades (three from Africa, two from Asia and two from Europe) can be identified which present a geographic correlation (Fig. 3).

Phylogenetic studies show that the Greek strain AP92 (clade Europe 2) and West African viruses (clade Africa 1) are the oldest CCHFV lineages. The AP92 strain was initially isolated from *Rhipicephalus bursa* tick in 1975 in Greece, and only a limited number of human cases has been associated with this lineage. Several studies showed that this lineage is strongly associated with

Fig. 3 Neighbor-Joining phylogenetic tree based on whole open reading frame of CCHFV S RNA segment (1446 nucleotides) computed using the Kimura 2-parameter method. Evolutionary analysis was conducted in MEGA software version 7.0.

Rhipicephalus spp. ticks. Genetic recombination is rare, but reassortment events are common in CCHFV, especially in the M RNA segment which encodes the envelope glycoproteins, Gn and Gc, involved in the attachment of the virus to the host cells. Detection of genetic clades in unrelated geographic regions is common, and can be explained by the passive transportation of the virus to distant regions across continents through migratory birds and livestock trade. The increasing number of whole genome CCHFV sequences is expected to elucidate further the molecular epidemiology of CCHF and increase the knowledge on the evolutionary history of the virus.

Clinical Features

Humans are the only vertebrates which present symptoms after CCHFV infection (Fig. 4),

CCHFV-infected humans may present asymptomatic, mild, severe, or even fatal disease. It is estimated that more than 80% of CCHFV infections are asymptomatic or subclinical and remain unnoticed. The case fatality rate (CRF) in hospitalized patients is 10%–40%. The course and outcome of the disease depend on the inoculation viral dose, the virus strain and the immune status and response of the host. In severe and fatal cases the production of antibodies is usually low, delayed or absent. CCHF resembles Ebola virus disease in clinical symptoms, underlying mechanisms and cytokine production.

Following initial virus amplification at the site of inoculation (dermal dendritic and Langerhans cells), the virus is spread through the lymphatic system to the target organs, mainly liver and spleen, and then is spread to additional organs. Endothelial damage leading to increased permeability and impaired immune response seem to play an important role in the clinical course and severity of the disease.

Typically, the clinical course follows four distinct phases: incubation, pre-hemorrhagic, hemorrhagic and convalescence. The incubation period is 1–14 days and varies depending on the viral dose and the route of exposure (it is usually shorter after a bloodstream infection, e.g., tick bite or needle-stick injury). The pre-hemorrhagic phase (1–5 days) is characterized by abrupt onset of fever lasting for 4–5 days, chills, severe headache, photophobia, conjunctivitis, fatigue, dizziness, myalgia, flushed face and rash, as well as gastrointestinal symptoms, such as nausea, vomiting, abdominal pain, and diarrhea. Hepatomegaly, jaundice, splenomegaly, pleural effusions and cardiovascular symptoms, such as bradycardia or tachycardia and hypotension, can be also seen. Some patients present changes in mood, confusion and aggression, followed by depression and somnolence. Patients with severe disease enter the hemorrhagic phase (3–4 days) and develop hemorrhagic manifestations on the mucous membranes and skin ranging from petechiae, epistaxis, bleeding at venipuncture and injection sites, ecchymosis, hematomas, and gingival hemorrhage

Fig. 4 Large hematomas in a Crimean-Congo hemorrhagic fever patient (day 10 of illness), Greece, 5 June 2018.

to severe hemorrhages from various systems (melena, hemoptysis, hematemesis, hematuria, nose and vaginal bleeding, and cerebral hemorrhage). Hemophagocytosis is often detected in the bone marrow biopsy. Necropsy findings in a fatal case in Spain revealed massive hepatocyte necrosis, complete apoptosis of colonic enterocytes, hemorrhages in bone marrow without inflammatory infiltrates in any of the organs examined providing support for the view that unlike other viral hemorrhagic fevers, there is a primary cytopathic pathogenic effect in CCHF. Death occurs 5–14 days after symptom onset. The survivors show improvement signs on the 10th day onwards, but recovery may be delayed by one month or even longer. Some persisting symptoms include weakness, lethargy, dizziness, hearing loss, and amnesia. The hospitalization time is approximately 10 days. The clinical course of the disease is usually milder in children.

The most frequently reported abnormal laboratory findings include thrombocytopenia, prolonged coagulation (prothrombin and activated partial thromboplastin) times, decreased fibrinogen, leucopenia, elevated levels of aminotransaminases, creatine phosphokinase, and lactate dehydrogenase. Collecting, handling and processing clinical samples require trained personnel and suitably equipped laboratories.

Differential diagnosis of CCHF includes other viral hemorrhagic fevers, rickettsiosis and other tick-borne bacterial infections, leptospirosis, viral hepatitis, brucellosis and bacterial sepsis, while non-infectious diseases may also cause similar symptomatology. Additional diseases have to be included when symptoms from respiratory, gastrointestinal or central nervous system are present. The list of diseases depends highly on the geographic location of the case and the travel history of the patient. The differential diagnosis is difficult when the patient presents only a mild flu-like illness.

Disease severity scoring systems have been developed. High viral load, severe thrombocytopenia, elevated liver enzymes and prolonged bleeding times are the most important predictors of severity and fatality in CCHF. Viral loads higher than 1×10^9 RNA copies/mL of plasma were strongly associated with fatality in CCHF patients. Specific HLA alleles and genetic polymorphisms in Toll-like receptors, as well as elevation of specific cytokines (e.g., IFN-inducible protein 10 and monocyte chemoattractant protein-1) and soluble adhesion molecules, have been also associated with severity and outcome of the disease.

Pathogenesis

CCHFV infection in human can result in a severe hemorrhagic fever. Interestingly, serological evidence indicates that CCHFV can infect numerous vertebrate species. However, even within humans, CCHFV infection may result in a mild or sub-clinical infection.

The factors contributing to development of a severe disease are unknown. The incubation period ranges from a few days up to 1 week, the length most probably depending on the transmission route and the amount of inoculum. The severity of disease has been demonstrated to correlate to the amount of virus in the blood. Furthermore, it has also been shown that antibody responses have a highly significant inverse correlation with viral loads. The pathogenesis of CCHF is only poorly characterized due to several reasons such as (1) infections occur sporadically and in areas where facilities are limited for performing complete autopsies, (2) virus handling requires biosafety level 4 (BSL-4) containment laboratories, and (3) a lack of available animal models of disease. The limited knowledge about CCHF pathogenesis is mostly derived from blood analyzes and liver biopsies of patients, using materials e.g., from outbreaks in Turkey and South Africa. One of the most comprehensive study involving 50 CCHF patients from South Africa, which describe that cerebral hemorrhage, severe anemia, severe dehydration, and shock associated with prolonged diarrhea, lung edema, and pleural effusion are the factors causing fatal outcome. Almost all patients who died developed multiple organ failure. In the fatal cases, platelet counts can be extremely low from an early stage of illness. Increases in aspartate and alanine aminotransferase (AST and ALT) levels in the serum, prolongation of prothrombin and partial thromboplastin times have also been observed.

A common suggested feature of agents causing hemorrhagic fever is the deregulation of host immune responses by combating and attacking cells involved in initiation of antiviral responses. The primary pathophysiological events appear to be leakage of erythrocytes and plasma through the vasculature into tissues. Endothelial damage can contribute to coagulopathy by deregulated stimulation of platelet aggregation, which in turn activates the intrinsic coagulation cascade, ultimately leading to clotting factor deficiency causing hemorrhages. For CCHFV, vascular leakage may be caused either by destruction of endothelial cells or by a disruption of the tight junctions which constitute the endothelial barrier between cells. Moreover, it is unclear whether these events are a direct consequence of infection or whether virus-induced host factors cause the endothelial dysfunction. However, in an epithelial cell line model CCHFV neither caused disruption of tight junctions nor necrosis or apoptosis of cells. This could suggest that the hemorrhages and coagulation disturbances may be caused indirectly, possibly by high levels of proinflammatory cytokines. Previous studies demonstrated higher level of IL-6 and TNF- α in CCHFV patients with fatal outcome compared to the non-fatal cases [38].

The ability of CCHFV to cause severe or lethal disease in mice deficient in the type I interferon system but not wild-type (WT) mice suggests that innate immune responses in vertebrate hosts play a substantial role in limiting CCHFV pathogenesis. Understanding the role of the adaptive immune response in the control of primary CCHFV infection has been limited by the lack of suitable animal models. However, a newly described humanized mouse model of CCHFV demonstrated that T cells were activated following CCHFV infection and may have a role in controlling the disease. In a recent study using mice treated with an interferon blockade antibody, demonstrating that adaptive immune responses can control CCHFV in mice. Recently a cynomolgus macaque model of CCHF for CCHFV has been described, in which cynomolgus macaques infected with a human clinical isolate of CCHFV, strain Hoti. These infected macaques develop a spectrum of disease outcome similar to that of human CCHF cases from asymptomatic to severe or lethal infections. Histological analysis showed that CCHFV infection resulted mainly in pathological changes in the liver and spleen.

In vitro studies have suggested retinoic acid-inducible gene I (RIG-I) as an innate immune sensor of CCHFV. However, it is most likely that more innate immune sensors contribute to sensing of CCHFV. The L segment of CCHFV encodes an ovarian tumor-like de-ubiquitinase (OTU) domain that recently has been shown to suppress innate immune responses. Several studies indicated that host apoptosis process may also be involved in the pathogenesis and controlling of CCHFV infection. There are a few studies in humans have identified correlates between polymorphisms in Toll-like receptors (TLRs), nuclear factor-kappa B and severity of disease. CCHFV also antagonizes innate immune signaling.

Diagnosis

Confirmation of infection early in the course of disease is important for isolation of patients to protect healthcare workers and for implementing appropriate supportive therapy. Although human cases can be identified using clinical criteria, laboratory confirmation is considered essential to distinguish the infection from other conditions that share similar manifestations.

Laboratory confirmation during the acute phase is achieved by isolation of the virus, amplification of viral nucleic acid using reverse transcriptase polymerase chain reaction (RT-PCR) or detection of viral antigen. The virus is classified among biosafety level 4 pathogens and hence culturing the virus is restricted to high containment facilities of which there are limited numbers worldwide. In the absence of level four facilities, clinical samples can be inactivated prior to testing.

Virus is most frequently isolated from clinical serum samples collected during the acute phase of illness from days 1–6 after onset of symptoms, although isolation has been reported from samples collected up to day 12. Although the virus replicates in a variety of mammalian primary and line-cell cultures, Vero cells are the most frequently used for routine isolation. The virus is poorly cytopathic and immunofluorescent assays are required to confirm infection of cells. Virus can also be isolated by intracerebral inoculation of 24 h old mice. Isolation of the virus in mice is usually more sensitive than cell culture but it requires 7–10 days for mice to succumb to infections whereas isolation in cell cultures can be confirmed within 3–6 days. Molecular techniques have distinct advantages over traditional virus isolation methods in that a result can be obtained far more rapidly and the assays can be performed using inactivated samples without the requirement for biosafety level four

facilities. The first diagnostic molecular assay was a conventional nested RT-PCR based on alignment of the NP gene of seven geographically distinct isolates of CCHFV and identification of consensus primer pairs. Since the development of the first in house RT-PCR, the availability of nucleotide sequence data for complete and partial genomes from various geographic regions and identification of genetic relationships, defining genotypes and their distribution, has contributed to further refinement of molecular assays. The availability of data allows design of molecular assays to accommodate nucleotide diversity and detect genetically different lineages. Real time RT-PCR platforms have been developed using simple intercalating dye and a melt curve analysis to detect amplicons; sequence specific probes with multiple primer pairs and probes to detect all lineages; low density macroarrays and padlock probes with colourimetric readout. Isothermal assays such as loop-mediated isothermal amplification (LAMP) and an isothermal recombinase polymerase assay have been described with potential for diagnostic application. Commercial molecular assays based on primer and probe technology are now available. Real time assays with probes allow quantification of viral load which has been used as a prognostic indicator and a high viral load can be considered to be a predictor of a fatal outcome.

Detection of viral antigen using ELISA has been described and although it may have a role in low resource laboratories it lacks the sensitivity required for use as a diagnostic tool. With the availability of molecular assays, including isothermal RT-RPA that can be performed without the need for thermal cyclers, viral antigen ELISA are unlikely to be important in a diagnostic facility. However detection of viral antigen in paraffin embedded tissues using immunohistochemistry is a useful tool for confirming infection in fatal cases although molecular assays can also be used to detect viral nucleic RNA in post mortem samples.

During the convalescent phase of illness, serological assays, such as in house or commercial ELISA and indirect immunofluorescent assays (IFA), are used for detection of IgG and IgM antibody. Human infections can be confirmed by detection of a specific IgM response, or alternatively, demonstration of seroconversion or at least a four-fold increase in IgG antibody activity in paired serum samples. An antibody response is most commonly detectable from day 5 after onset of illness in non-fatal cases, whereas in fatal infections patients may not develop demonstrable antibody responses.

Although assays such as targeted amplification and next generation sequencing based identification, Taqman cards and multiplexed Luminex based immunoassays have been investigated as diagnostic tools, the usefulness of these techniques will likely be limited by accessibility to suitable equipment and cost effectiveness in routine application. The need for rapid sensitive and specific point of care assays remains a requirement for increasing diagnostic capacity.

In summary, diagnosis of human infections is usually achieved using a combination of assays including isolation of virus, detection of CCHF viral RNA and demonstration of antibody response. Interpretation of results for exclusion or confirmation of infection usually requires an accurate history of illness and consideration of kinetics of viremia and antibody responses.

Prevention

The CCHFV constitutes a public health risk in endemic countries as well as neighboring areas. To date, WHO put CCHFV in their blue print and highlight the importance on developing vaccines and treatment for this virus. A vaccine against CCHFV will prevent infection in human populations at risk, and reduce the number of cases of CCHF. To date, there is a licensed vaccine against CCHFV available in Bulgaria. This vaccine has been developed in 1970 in Russia and is based on CCHFV cultivated in suckling mouse brain and subsequently inactivated by chloroform, heated at 58°C, and absorbed on Al(OH)₃.

Data from the Bulgarian Ministry of Health suggest a fourfold reduction in reported CCHF cases since they used this vaccine in Bulgaria. However, this observation can be due a several factors which have decreased tick exposure in the region per se. The first detailed analysis of the cellular and humoral immune response in healthy individuals following vaccination with the Bulgarian vaccine demonstrated that vaccinated individuals developed anti-CCHFV immunity however, responses were low and required three booster vaccinations to improve immune responses. It should also be highlighted that the use of mouse brain derived vaccine unlikely gain widespread international regulatory approval due to several reasons such as possibility to autoimmune responses induced by myelin basic protein and etc.

The most obvious problem for development of vaccine candidates against CCHFV, has been the lack of a good animal models. Whilst studies on the immunogenicity of vaccine candidates can increase our knowledge on immune response to these candidates, the outcome are difficult to interpret as no defined immune correlate of protection is available. Nevertheless, to date there are two mice model available which make it possible to assess the protection studies.

The data on vaccine candidates for CCHFV are presented in (Table 1), and the vaccine candidate which has demonstrated efficacy data are discussed in more detail below.

DNA Vaccines

Recently, A DNA vaccine coding for CCHFV Gc, Gn and NP demonstrated induction of both humoral and cell-mediated immune responses which elicited complete protection from lethal disease in a mouse model. A DNA vaccine expressing only the M-segment glycoprotein precursor gene of CCHFV elicited strong antigen specific humoral immune responses with neutralizing titers after three vaccinations, demonstrated 75% protection and highlight that a DNA vaccine expressing the glycoprotein genes of CCHFV elicits protective immunity against CCHFV.

Table 1 Approaches for human vaccines against CCHFV

Inactivated Vaccines

To date there is a report on a vaccine candidate based on a purified, formalin inactivated of CCHFV derived from cell culture which avoid the complications of a mouse brain derived vaccine (the Bulgarian licensed vaccine). Vaccination with this inactivated virus required the use of adjuvant. The efficacy in the IFNAR^{-/-} mouse model of CCHF showed 80% protection using this vaccine candidate,. While inactivated virus vaccines have proven effective for protecting against many viral diseases, those based on highly pathogenic viruses such as CCHFV are difficult to manufacture in bulk within a high containment setting.

Modified Vaccinia Virus Ankara (MVA)

There is a report describing a MVA poxvirus vector containing the glycoprotein encoding M segment ORF (MVA-GP). This vaccine candidate demonstrated 100% efficacy in animal studies. This MVA-GP vaccine induced antibody and cellular responses across a range of CCHFV epitopes. MVA platform has a proven safety record, having been used in the latter stages of the smallpox eradication campaign, and it is thermostable avoiding the requirement to maintain a cold chain and conferring an extra advantage for regions where such a vaccine might be used.

Adenovirus Vaccine

A human serotype 5 adenovirus (AdHu5) vector carrying the M segment of CCHFV has been investigated as a vaccine candidate using IFNAR^{-/-} mice. Despite the induction of both cellular and humoral responses, the vaccine failed to confer protection in a murine model. Recently, using a construct of human adenovirus type 5 expressing the CCHFV N protein, it was demonstrated that mice immunized with Ad-N developed an anti-N humoral immune response. It was shown that a prime-boost of this vaccine candidate regimen provided 78% protection.

Treatment

The current medical management is largely supportive and on the treatment of symptoms. To date, there are no licensed specific antiviral compounds available for CCHF. Ribavirin, a broadspectrum antiviral drug, has been used as a common treatment approach. Several reports have suggested clinical benefits of using ribavirin, especially if administered early in infection. However, recently several studies have reported no effect on mortality rates. Recent studies have shown that T-705 (favipiravir) has a higher efficacy than ribavirin in animal model. It should be also highlighted that there are other reports demonstrating antiviral activity for several compounds against CCHFV, however, these studies are in vitro. The lack of efficient treatment and vaccines options, emphasizes the urgency for developing CCHF therapeutics.

Glossary

Arbovirus A virus transmitted to vertebrates by hematophagous (blood-feeding) arthropods.

Endemic A disease constantly present in a specific geographic region.

Extrinsic incubation time The time between infection and becoming infectious.

Hyperendemicity The co-circulation of multiple dengue virus serotypes in the same population.

Vertical transmission Transmission of a virus from a female arthropod to its progeny.

History

Dengue fever is a very old disease; the earliest record of a dengue-like illness found to date is in a Chinese encyclopedia of disease symptoms and remedies, first published during the Chin Dynasty (AD 265–420) and formally edited in AD 610 (Tang Dynasty) and again in AD 992 during the Northern Song Dynasty. There are reports of epidemics of dengue-like illnesses in the French West Indies in 1635 and in Panama in 1699. By the late 1700s, a disease clinically compatible with dengue had spread worldwide, with epidemics occurring in 1779 in Batavia (Jakarta), Indonesia and Cairo, Egypt, and in 1780 in Philadelphia, Pennsylvania, USA. From the late 1700s to World War II, repeated epidemics of dengue-like illness occurred in most tropical and subtropical regions of the world at 10- to 40-year intervals. There is no documentation, however, that dengue viruses were responsible for all of these epidemics because the diagnosis was based only on clinical reports. Clinical descriptions of some early epidemics were also compatible with chikungunya virus infection, which has a transmission cycle similar to that of the dengue viruses. It is likely that epidemic chikungunya did occur, but recent data show that the dengue viruses, not chikungunya virus, were responsible for the majority of epidemics in the past 60 years.

The virus etiology of dengue fever was not documented until 1943–44, when Japanese and American scientists simultaneously isolated the viruses from soldiers in the Pacific and Asian regions during World War II. Albert Sabin isolated dengue viruses from soldiers who became ill in Calcutta (India), New Guinea, and Hawaii. The viruses from India, Hawaii, and one strain from New Guinea were antigenically similar, whereas three others from New Guinea were different. These viruses were called dengue 1 (DENV-1) and dengue 2 (DENV-2) and designated as prototype viruses (DENV-1, Hawaii, and DENV-2, New Guinea C). The Japanese virus, isolated by Susumu Hotta, was later shown to be DENV-1. Two more serotypes, called dengue 3 (DENV-3) and dengue 4 (DENV-4), were subsequently isolated by William McD. Hammon and his colleagues from children with hemorrhagic disease during an epidemic in Manila, the Philippines, in 1956. There have been viruses isolated that were suspected to represent new DENV serotypes, but characterization remains ongoing and identification of additional DENV serotypes has not been confirmed.

Many early workers suspected that dengue viruses were transmitted by mosquitoes, but actual transmission was first documented by H. Graham in 1903. In 1906, T. L. Bancroft demonstrated transmission by *Aedes aegypti*, later known to be the principal urban mosquito vector of dengue viruses. Subsequent studies in the Philippines, Indonesia, Japan, and the Pacific showed that *Aedes albopictus*, *Aedes polynesiensis* and other members of the *Aedes* (*Stegomyia*) *scutellaris* complex were also efficient secondary vectors for dengue viruses.

During and following World War II, *A. aegypti* greatly expanded its distribution in Asia, becoming the dominant day-biting mosquito in most Asian cities. Multiple dengue virus serotypes were also disseminated widely at that time. At the end of the war, both the vector (*A. aegypti*) and the viruses (all four serotypes) were widespread in Asia. A dramatic increase in human population growth and urbanization in the postwar years, especially in southeast Asia, created ideal conditions for increased transmission of urban mosquito-borne diseases. As a result, epidemics of dengue became widespread in the region. The first epidemics where dengue hemorrhagic fever (DHF) was reported occurred in the Philippines and Thailand in the mid 1950s. In the 1960s, but accelerating in the 1970s–80s, jet air travel increased dramatically. Population growth and urbanization combined with increased movement of people within and among countries of the region, resulted in increased spread of dengue viruses among population centers, increased frequency of epidemic activity, the development of hyperendemicity (co-circulation of multiple dengue serotypes), and the emergence of epidemic dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS) in the countries of southeast Asia and India during the 1960s. During the 1970s, epidemic DHF/DSS expanded geographically with an accelerated rate in Asia, to the Pacific Islands after an absence of 25 years, and to the Americas. *A. aegypti* had been eradicated from many countries in tropical America in the 1950s and 1960s as part of a program to control urban yellow fever. The program was terminated in the early 1970s and *A. aegypti* began reinfesting the countries where it had been eliminated. Increased epidemic dengue fever followed as the region was reinfested by *A. aegypti* and new viruses were introduced during the 1970s, 1980s, and 1990s.

With the development of global hyperendemicity in the tropics, severe dengue has emerged as one of the world's most important global public health problems in the 21st century. It is a leading cause of hospitalization and death among children in tropical developing countries and causes a high economic and social toll where the disease is endemic. Epidemics occur frequently.

Fig. 1 Global distribution of dengue fever and its principal epidemic mosquito vector, *Aedes aegypti*, 2019.

In 2020, dengue fever is the most important arboviral disease of humans, with more than half of the world's population (an estimated 3.6 billion people) living in areas at risk for dengue in tropical and subtropical areas of the world (Fig. 1). An estimated 400 million dengue infections occur each year. The average case–fatality rate for patients with severe dengue is variable, depending on the country, but averages about 5%.

Taxonomy and Classification

Dengue viruses belong to the family *Flaviviridae*, genus *Flavivirus*. There are four serotypes: DENV-1, DENV-2, DENV-3, and DENV-4. Dengue viruses belong to a larger, heterogeneous group of viruses called arboviruses. This is an ecological classification that requires transmission between vertebrate hosts, including humans, and hematophagous arthropod vectors. A discussion of the epidemiologic, evolutionary, biologic, and immunologic relationships of these viruses with each other and with other flaviviruses is beyond the scope of this article.

As are other flaviviruses, dengue viruses are comprised of a single-stranded positive sense RNA genome surrounded by an icosahedral nucleocapsid. The latter is covered by a lipid envelope, which is derived from the host cell membrane from which the virus buds. The mature virion is approximately 50 nm in diameter (Fig. 2). The virus genome encodes three structural and seven nonstructural proteins in a single open reading frame that are expressed as one polyprotein. The open reading frame is flanked by two non-coding regions. The three structural proteins include the nucleocapsid core (C), a membrane associated protein (M), and an envelope (E) glycoprotein. The seven non-structural proteins include the NS1, NS2A, NS2B, NS3, NS4A, NS4B and NS5 (Fig. 3). The functional domains responsible for virus neutralization, hemagglutination, fusion, and interaction with virus receptors are associated with the E protein. Epitope mapping has demonstrated three major domains on the E protein. Immunogenic epitopes have been mapped to all three domains, but domain II appears to be most important for dengue virus neutralization.

There are 53 virus species in the genus *Flavivirus* recognized by the International Committee on Taxonomy of Viruses. The flaviviruses are divided into four subgroups based on the mode of transmission: (1) insect-specific viruses that have only been isolated from various mosquito species; (2) viruses that have no known arthropod vector, and which have been isolated only from rodents and bats; (3) mosquito-borne viruses; and (4) tick-borne viruses. The mosquito-borne and tick-borne groups are the largest, but many insect-specific viruses have been identified in recent years. The dengue viruses belong to the mosquito-borne subgroup, and are considered as one virus species with four serotypes instead of four distinct viruses according to the current classification. Other members of the mosquito-borne group that are of public health importance include the genus prototype yellow fever virus, and Japanese encephalitis, Murray Valley encephalitis, St. Louis encephalitis, West Nile, Zika and others.

Trends in Microbiology

Fig. 2 Mature Dengue Virus (DENV) Structures. (A) A quarter of the central cross-section of a cryoEM map of DENV. The map is colored radially: red (1–130 Å), yellow (131–200 Å), green (201–234 Å), cyan (235–249 Å), and blue (>250 Å). The part of the DENV structure colored in red and yellow indicates the approximate radius that contains the RNA–capsid proteins complex. In green, the lipid bilayer membrane is shown with the E and M transmembrane regions; cyan indicates the E and M ectodomains, and blue indicates the glycosylation sites of E and M proteins. (B) Crystal structure of the prefusion dimeric E protein [Protein data bank (PDB) 1OAN]. DI, DII, and DIII are colored in red, yellow, and blue, respectively. The fusion loop on each E protein is circled in black. (C) Crystal structure of the postfusion trimeric E proteins (PDB 1OK8). One E protein is colored as indicated in (B), the other two are shown in gray. Fusion loops are assembled at one end (enclosed in the black box) and likely interact with the endosomal membrane. (D) Organization of E proteins on the compact mature DENV at 28°C (PDB 3J27). Ribbon representation of an E protein raft is shown. One asymmetric unit contains three individual E proteins: mols A, B, and C. The neighboring symmetry-related E proteins within a raft are labeled as A', B', and C'. All E proteins on the virus surface are also shown as gray surfaces. The 5- and 3-fold vertices are indicated by red pentagon and triangle shapes, respectively. (E) The cryoEM structure of the DENV2 class III particles at 37°C (PDB 3ZKO). All of the E proteins have moved to higher radius. The E protein dimer near the 5-fold vertex (mols A–C') has undergone rotation. The B and B' dimer dissociate from each other. *Source:* Lok, S.-M., 2016. The interplay of dengue virus morphological diversity and human antibodies. *Trends in Microbiology* 24 (4), 284–293.

Fig. 3 Organization of the dengue virus genome.

Antigenically, the dengue viruses make up a unique complex within the mosquito-borne group of *flaviviruses*. Although the four dengue serotypes are antigenically distinct, there is evidence that serologic subcomplexes may exist within the group. For example, a close genetic relationship has been demonstrated between DENV-1 and DENV-3 and between DENV-2 and DENV-4. The sizes of the genomic open reading frames of DENV-1, DENV-2, DENV-3, and DENV-4 are 3392, 3391, 3390, and 3387 amino acids, respectively, the shortest among the mosquito-borne flaviviruses. An amino acid sequence positional homology of 63%–68% is observed among the DENV serotypes compared to 44%–51% between DENVs and other flaviviruses such as yellow fever and West Nile.

Geographic and Seasonal Distribution

Dengue viruses have a worldwide distribution in tropical and subtropical areas (**Fig. 1**). The viruses are endemic in most urban centers of the tropics, with transmission occurring year-round, and epidemics occurring every 3–5 years. It is well documented, however, that dengue viruses are maintained for the most part by silent transmission during interepidemic periods in most tropical urban areas and, although the risk of infection is lower than during epidemic periods, there is still substantial risk for infection.

Peak seasonal transmission of dengue viruses during both epidemic and interepidemic periods is usually associated with periods of high rainfall and moderated temperature in most endemic countries. Factors influencing seasonal transmission patterns of dengue viruses are not well understood, but obviously includes mosquito density, which may increase during the rainy season, especially in those areas where water level in larval habitats is dependent on rainfall. In areas where water in storage containers is not influenced by rainfall, however, other factors such as higher humidity and moderate ambient temperatures associated with the rainy season increases survival of infected mosquitoes, thus increasing the probability of secondary transmission. Virus strain, serotype, herd immunity, mosquito species, mosquito behavior and mosquito vector competence also influence the transmission dynamics.

Host Range and Virus Propagation

There are only three known natural hosts for dengue viruses: *Aedes* mosquitoes, humans, and non-human primates. Viremia in humans may last 2–12 days (average, 4–5 days) with titers of infectious virus ranging from undetectable to more than 10^8 mosquito infectious doses 50 (MID₅₀) per ml. Experimental evidence shows that several species of primates (chimpanzees, gibbons, and macaques) become infected and develop viremia titers high enough to infect mosquitoes, but do not develop illness. Viremia levels in lower primates are more transient, often lasting only 1–2 days if detectable, with titers seldom reaching 10^6 MID₅₀ per ml. However, recent studies in Cambodia have suggested that humans with undetectable viremias by PCR were still capable of infecting mosquitoes. This has important implications for virus maintenance during interepidemic periods.

Dengue viruses are known to cause clinical illness and disease only in humans and some non-human primates. Baby mice, which are used for the isolation and assay of many other arboviruses, may show no signs of illness after intracerebral inoculation with most unpassaged strains of dengue viruses. Experimentally, however, some strains can be adapted to produce illness and death in baby mice by serial passage. SCID, Rag^{2-1-8c-1} and AG129 mice have been used for pathogenesis studies since these immunocompromised strains have defects either in innate or adaptive immune responses, allowing robust viral replication. Some strains of dengue, primarily low passage clinical isolates, are also capable of replicating transiently in immunocompetent mice.

Mosquito species of the genus *Aedes* appear to be the natural hosts for dengue viruses. Species of the subgenus *Stegomyia* are the most important vectors in terms of human transmission, and include *A. (S.) aegypti*, the principal urban vector worldwide, *A. (S.) albopictus* (Asia, the Pacific, Americas, Africa, and Europe), *A. (S.) scutellaris*, *A. (S.) polynesiensis*, *A. (S.) hensilli*, *A. (S.) pseudoscutellaris* (Pacific), *A. (S.) africanus*, *A. (S.) taylori* and *A. (S.) luteocephalus* (Africa). It is uncertain what role *A. albopictus* plays in transmission in areas where it has been recently introduced. Species of the subgenera *Finlaya* (Asia) and *Diceromyia* (Africa) appear to be important mosquito hosts involved in forest maintenance cycles of these viruses. Two other species, *Ochlerotatus* (= *Aedes*) (*Gymnotetop*) *mediovittatus* (Caribbean) and *Oc. (=Aedes)* (*Protomacleaya*) *triseriatus* (North America), have been shown to be excellent experimental hosts of dengue viruses.

Low passage or unpassaged dengue viruses can efficiently be propagated only in laboratory-reared mosquitoes and in mosquito cell lines. Mosquito species most commonly used for in vivo propagation include *A. aegypti*, *A. albopictus*, and *Toxorhynchites* spp., all of which can be reared with ease in the laboratory. Only three mosquito cell lines show high susceptibility to dengue viruses: C6/36 from *A. albopictus*, AP-61 from *A. pseudoscutellaris*, and TRA-284 from *T. amboinensis*.

Dengue viruses can also be propagated in baby mice (see above) and in several vertebrate cell lines. These infection models have lower susceptibility to infection than the mosquito cells. However, dengue viruses must be adapted to each system by serial passage before consistent results can be obtained. Mammalian cell lines commonly used include LLC-MK2 and VERO (monkey kidney), BHK-21 (baby hamster kidney), FRhL (fetal rhesus lung), and PDK (primary dog kidney) cells. Propagation of dengue viruses in mosquito cell lines is associated with genetic stability due to slower accumulation of mutations than propagation in mammalian cell lines.

Genetics

Laboratory and epidemiologic studies have demonstrated that genetic variants of dengue viruses occur in nature. This was first observed with DENV-3 isolated during the epidemics in Puerto Rico in 1963 and 1977, and in Tahiti in 1965 and 1969. The viruses in these epidemics were shown to be antigenically and biologically very similar to each other, but very different biologically from Asian strains of the same serotype. Antigenic differences were observed between Caribbean and Asian strains of DENV-4 as well.

Oligonucleotide fingerprinting, restriction enzymes, primer extension, sequencing, and nucleotide sequence comparisons have been used to study the genetic variation among dengue viruses. The number of genetic subtypes identified in each serotype varies with the method used, but based on sequencing of the envelope protein, there are five distinct genotypes of DENV-1, five of DENV-2, four of DENV-3, and four of DENV-4. In general, viruses circulating in the same geographic region during the same time periods have shown genetic homogeneity, while differing from viruses of the same serotype from other regions. However, with increased transmission and spread of dengue viruses worldwide via airplane, they have increased in diversity, influencing both the virulence and epidemic potential. Since there is not an ideal animal model for dengue, it is not well understood how genetic changes or variation influences phenotypic expression of the viruses. That said, however, epidemiologic, clinical and virologic evidence is accumulating showing the importance of the virus strain in determining disease severity and epidemic potential.

Genetic evidence of the diversity of dengue viruses influencing transmission dynamics comes from clinical and epidemiological studies in a series of epidemics in Asia, the Pacific and Caribbean Islands from the 1970s to the present time. In the earlier studies, viruses were isolated and stored unpassaged at -70°C for years until technological advances allowed their study. Full-length genome sequencing was conducted on viruses isolated before, during and after these epidemics where DENV-2, -3 and -4 were predominant. Epidemiological and sequence data from three geographic regions (Asia, Pacific and Americas) and all three serotypes (DENV-2, -3 & -4) show limited genetic changes in the viruses (two-three amino acid changes mainly in the non-structural genes) correlated with phenotypic changes, including clinical severity, viremia levels in humans, virus replication in mosquitoes and cell culture, and epidemic potential. More recent studies have defined the molecular basis for phenotype changes of DENV-1 and -2. Collectively, the data suggest that dengue virus evolution via genetic drift and positive selection may result in the emergence of new virus clades or subtypes, often of the same genotype, that have greater epidemic potential, thus playing an important role in the epidemiology and pathogenesis of severe dengue. Epidemic potential, disease severity and pathogenesis of dengue are determined by a complex interaction of viral, host and environmental factors.

Although there have been reports on intraserotypic recombination events among dengue viruses, the data suggest that this has not been an important factor in their evolution. However, with increased occurrence of the cocirculation of multiple serotypes in an area (hyperendemicity), there have been increased reports of concurrent infections with two serotypes increasing the probability that interserotypic recombination may occur.

Evolution

The origin of dengue viruses is not known. It is not clear which of the four flavivirus groups (insect specific, vertebrate, mosquito-borne, tick-borne) is the oldest. Given the large number of insect-specific viruses identified in mosquitoes in recent years, which have tentatively been placed in the genus *Flavivirus*, however, it seems plausible that an ancestral flavivirus was a mosquito or a tick virus that diverged by adapting to a variety of vertebrate hosts, including rodents, birds, bats, and nonhuman primates. From these early introductions, the no-known vector, tick-borne encephalitis, and mosquito-borne (yellow fever, dengue, and Japanese encephalitis) subgroups arose. Speculation that tick-borne and mosquito-borne viruses had a common ancestor is supported by

the fact that several mosquito-borne flaviviruses (Koutango, Saboya, West Nile, St. Louis encephalitis and yellow fever) have all been isolated from ticks. Also, it has been reported that some tick-borne viruses replicate in mosquitoes or mosquito cell cultures. On the other hand, a comprehensive replication study of 66 flaviviruses in mosquito, tick, and vertebrate cell cultures showed conclusively that there is a strict host range specificity for viruses in the four subgroups, and that the conventional classification based on epidemiologic and phylogenetic relationships is correct.

Regardless of the geographic and evolutionary origin, the data collectively suggests that the dengue viruses most likely evolved in mosquitoes before becoming adapted to lower primates and then to humans, an estimated 1500–2000 years ago. Biologically, dengue viruses are well adapted to their mosquito hosts, being maintained by vertical transmission (from female mosquito to its offspring) in mosquito species responsible for sylvatic cycles, with periodic amplification in lower primates.

As noted above, forest cycles have been documented in South-East Asia and Africa, and possibly in Sri Lanka, India, Vietnam and China. These cycles involve several species of lower primates and three subgenera (*Stegomyia*, *Finlaya*, and *Diceromyia*) of canopy-dwelling mosquito species of the genus *Aedes*. At some point in the past, probably with the clearing of the forests and development of human settlements in Asia, these viruses moved out of the jungle and into a rural environment where they were, and still are, transmitted to humans by peridomestic mosquitoes such as *A. albopictus*. Ultimately, the migration of people moved the viruses into the cities of the tropics where they became “urbanized” and transmitted by the highly domesticated, urban *A. aegypti* mosquito, which had been spread around the world from Africa via sailing ships and increased commerce.

Because of the rather slow rate of change (genetic drift) of the dengue virus genome, viruses isolated over long periods of time in the same geographic region still show striking homogeneity. The greatest genetic differences between dengue virus strains were observed between DENV-2 and DENV-3 isolated from forest mosquitoes in Africa and Asia, respectively, and viruses of the same serotype isolated from humans or mosquitoes in nearby urban areas. This suggests that there is limited gene flow between the forest and urban cycles.

Serologic Relationships and Variability

Dengue viruses share a common morphology, genomic structure, and antigenic determinants with 52 other flaviviruses. Serologic tests most frequently used to determine antigenic relationships have included the hemagglutination-inhibition (HI), complement fixation (CF), and the plaque reduction neutralization (PRNT) tests. Because all flaviviruses share common antigenic determinants, identification of individual family members using these serologic tests is difficult. The dengue viruses make up one antigenic complex within the genus *Flavivirus*. They share complex-specific antigenic determinants on both structural and nonstructural proteins. Serotypes within the dengue virus complex are most accurately and easily identified with an indirect immunofluorescent antibody (IFA) assay using serotype-specific monoclonal antibodies which react with epitopes on the structural proteins, or by a polymerase chain reaction (PCR) using serotype specific primers.

Both antigenic and biological variation among dengue viruses has been documented. As mentioned above, DENV-3 viruses isolated in the Caribbean and the South Pacific in the 1960s were found to be antigenically distinct from the prototype and Asian strains of DENV-3 using PRNT. They were also biologically unique in that they did not grow as well in baby mice and mosquitoes as did the Asian strains. DENV-4 viruses isolated in the Caribbean after the introduction of this serotype into that region in 1981 were antigenically distinct from DENV-4 viruses from Asia.

Field and epidemiological evidence for natural strain variation among dengue viruses is more circumstantial. When DENV-2 was introduced into the South and Central Pacific islands in 1971 after being absent for more than 25 years, epidemics occurred on numerous islands. Marked variation was observed in disease severity, viremia levels, and epidemic potential in epidemics on different islands. This variation was observed with both DENV-1 and DENV-2 in the Pacific and with DENV-3 in Sri Lanka and Indonesia. Some DENV strains appeared naturally attenuated, causing mild illness with low viremia levels of short duration, whereas others caused rapidly spreading epidemics with severe hemorrhagic disease and high viremia levels. Factors that could influence epidemic transmission and disease severity, other than differences in the virus strain, were ruled out as a cause of this variation. Recent studies in Sri Lanka and Puerto Rico have shown that genetic mutations in strains of DENV-3, DENV-2 and DENV-4 have also influenced the epidemic transmission potential of the virus and the disease severity.

Epidemiology

Dengue viruses occur in nature in three basic maintenance cycles. The primitive forest cycle involves canopy-dwelling mosquitoes and lower primates. A rural cycle, primarily in Asia and the Pacific, involves peridomestic mosquitoes (*A. albopictus* and *A. scutellaris* spp.) and humans. The urban cycle, which is the most important epidemiologically and in regard to public health and economic impact, involves the highly domesticated *A. aegypti* mosquito and humans. The viruses have fully adapted to humans and are maintained in most large urban centers of the tropics, with epidemics occurring at periodic intervals of 3–5 years.

A combination of increased urbanization in the tropics, changing life styles, and the lack of effective mosquito control has made most tropical cities highly permissive for transmission of dengue viruses by *A. aegypti*. Increased air travel by humans provides an ideal mechanism to transport dengue viruses between population centers. As a result, in the past 50 years there has been a dramatic global increase in the geographic spread of dengue viruses within and among regions, resulting in increased

epidemic activity, development of hyperendemicity, and increased incidence of severe and fatal forms of the disease, especially DHF/DSS. After being observed only in Southeast Asia, epidemic DHF/DSS has spread to west Asia, the Peoples Republic of China, Taiwan, the Pacific islands, the Americas, Africa and the Middle East in the past 50 years.

Factors responsible for the emergence and spread of the severe form of the disease, DHF/DSS, are not fully understood. The changing disease pattern described above provides support for the principal hypotheses regarding the pathogenesis of DHF/DSS, a secondary infection, and an increased virulence of the virus. Thus, increased transmission in urban areas and the development of hyperendemicity increases the probability of secondary infections and of genetic changes in the virus which may result in more severe disease due to antibody dependent enhancement (ADE) or to an epidemic virus strain with greater virulence. And increased spread of viruses between population centers via modern transportation increases the probability of introducing a virus strain with increased epidemic potential and virulence into new geographic areas.

Increased transmission of multiple dengue serotypes thus increases the probability that severe disease will occur, regardless of whether the underlying cause is due to increased virulence, ADE, or, more likely, a combination of both.

Dengue is primarily an urban disease. Most major epidemics of DHF/DSS occur in tropical urban cities where large and crowded human populations live in intimate contact with the principal mosquito vector, *A. aegypti*. This mosquito is a highly domesticated, day-biting species that lives and breeds in and around people's homes. High mosquito densities often occur in tropical cities because of water-storage practices and the accumulation of domestic waste. Primary larval habitats for *A. aegypti* include a variety of domestic water-storage containers such as clay jars and pots, metal drums, cement cisterns, and many other artificial containers found in the domestic environment that collect and hold rain water. The latter include, but are not limited to flower vases and pots, used automobile tires, buckets, bottles, cans, old machinery, etc.

Transmission and Tissue Tropism

Dengue virus transmission occurs mostly by bites of infective mosquito vectors. Any of the four serotypes may cause high levels of viremia in humans ($\geq 10^8$ MID₅₀ per ml) that lasts on an average of 4–5 days (range, 2–12 days). If a competent mosquito vector takes a blood meal from a person during a viremic phase, virus is ingested with the blood meal and infects the cells of the mosquito mesenteron. After 8–12 days, depending on ambient temperature and the strain of mosquito, the virus will disseminate outside the midgut and infect other tissues, including the mosquito ovaries, nerve ganglia, brain and salivary glands. When the mosquito takes a subsequent blood meal, virus is injected into the person along with the salivary fluid. Dengue virus infection has no apparent effect on the mosquito, which is infected for life.

A. aegypti is a highly competent epidemic vector of dengue viruses. It lives in close association with humans because of its preference to lay eggs in artificial water-holding containers in the domestic environment, and to rest inside houses and feed on humans rather than other vertebrates. It has a nearly undetectable bite and it is very restless in that the slightest movement will interrupt its feeding and make it fly away. It is not uncommon, therefore, for a single mosquito to bite several persons in the same room over a short period of time. If the mosquito is infective, every person bitten may become infected.

In addition to transmitting the virus to humans or non-human primates, the female mosquito may also transmit the virus vertically through her eggs to her offspring. Although the implications of vertical transmission are not fully understood, it is thought to be an important mechanism in the natural maintenance cycles of dengue viruses, especially in rural and forest settings.

The primary site of replication of dengue viruses after injection into humans by the feeding mosquito is not well understood. Infective mosquitoes will often probe the skin multiple times when looking for a blood vessel on which to engorge. Each time it probes, an infective mosquito injects salivary fluid infected with dengue viruses. Dengue viruses deposited in the epidermal and dermal layers likely infect a variety of cells, including dendritic cells, macrophages (Fig. 4). Additional responding cells such as mast cells, T cells, NK cells and others may be activated (Fig. 4). It is uncertain how systemic infection evolves, but it is likely that cells infected in the skin are recruited into the lymphatic system, allowing the infection to spread to the draining lymph nodes and beyond. Human tissues from which dengue viruses have been isolated or have had documented infection include liver, lungs, kidneys, lymph nodes, stomach, intestine, spleen and brain, but it is not known to what extent the virus replicates in these tissues. Infected cell types that have been identified include Langerhans cells, dermal dendritic cells, endothelial cells and macrophages and monocytes. Virus replication has also been detected in hepatocytes and Kupffer cells in the liver. Pathological changes similar to those observed in yellow fever, with focal central necrosis, have been observed in the liver of some patients who have died of dengue virus infection. There is some evidence that the viruses also replicate in endothelial cells and possibly in bone marrow cells. Encephalopathy has been documented in dengue infection but whether dengue viruses cross the blood–brain barrier and replicate in the central nervous system is still an open question. Dengue viruses have been transmitted by blood transfusion and organ transplantation.

Pathogenesis

Dengue disease expression in humans is the result of the complex interaction between an individual with specific genetic and immunological characteristics and the strain of dengue virus with specific virulence and biological characteristics. The result may range from asymptomatic infection to a severe disease and death. Unfortunately, animal models do not fully replicate the symptoms and kinetics of human infections, which vary greatly. Most of what we know or think we know is based on in vitro

Fig. 4 Host responses to cutaneous dengue virus. Most infections by dengue virus (DENV) occur after subcutaneous injection of the virus into the skin. Released viral particles may infect nearby cells such as monocytes or dendritic cells (DCs) or activate resident immune cells like mast cells. A local inflammatory response to DENV in the skin induces the recruitment of leukocytes from the vasculature, including natural killer (NK) cells and T cells, which promote the killing of virus-infected cells at the site of injection. DENV is thought to then travel to draining lymph nodes via lymphatic vessels to establish systemic infection. These localized inflammatory responses occur days before there are any signs of severe infection. *Source:* St. John, A.L., Abraham, S.N., Gubler, D.J., 2013. Barriers to pre-clinical investigations of anti-dengue immunity and immune-pathology. *Nature Reviews Microbiology* 11 (6), 420–426.

studies using highly passaged (adapted) viruses and artificial host systems, although low-passage clinical isolates are increasingly used for experimental studies. Therefore, there is still considerable controversy about the pathogenesis of severe dengue disease, including DHF/DSS.

Disseminating virus is first detected in the draining and remote lymph nodes, leading to a systemic infection and viremia, which may be detectable 24–48 h prior to clinical symptoms. Leukopenia, neutropenia and thrombocytopenia are common, with altered bone marrow cellularity. Evidence suggests that at least two pathogenetic mechanisms are associated with severe dengue infection. Classical DHF/DSS is characterized by a vascular leak syndrome which, if not corrected, may rapidly lead to hypovolemia, shock, and death (Fig. 5). Multiple theories of dengue pathogenesis exist and these primarily focus on the role of immune-mediated pathology in the initiation of vascular leak syndrome. In secondary infections, the mechanisms implicating non-neutralizing antibodies, or weakly cross-reactive T cells in generating high viral titers have been proposed to contribute to severe disease. The underlying pathogenetic mechanism for this syndrome is thought to be an immune enhancement phenomenon in which the infecting virus complexes with non-neutralizing dengue antibodies, thus enhancing infection of mononuclear phagocytes. Phagocytes produce vasoactive mediators, which may result in vascular permeability and leakage. Serum anti-dengue virus antibody levels may also be a factor in antibody-mediated pathologies. Moderate concentrations of cross-reactive antibodies are thought to promote enhanced disease severity, whereas low concentrations may be insufficient to induce the phenomenon and high concentrations could offer some cross-protection. Poorly neutralizing cross-reactive antibodies are also able to induce enhanced activation of mast cells, which release vasoactive mediators. Another hypothesis emphasizes the

Fig. 5 Clinical symptoms and pathogenesis of dengue in humans, across the spectrum of mild to severe disease. *Source:* St. John, A.L., Abraham, S.N., Gubler, D.J., 2013. Barriers to pre-clinical investigations of anti-dengue immunity and immune-pathology. *Nature Reviews Microbiology* 11 (6), 420–426.

importance of T cells in the clearance of dengue-infected cells. During secondary infection, memory recall responses by T cells that are only weakly cross-reactive for the secondary strain may exhaust immune resources and outcompete naïve T cells that would be more specific for the strain causing secondary infection. These activated T cells may also produce cytokines, in addition to infected cells, that could promote vascular leakage. Several vasoactive cytokines and host inflammatory factors have been identified in different human studies as being associated with severe dengue syndrome, including TNF, VEGF, and mast cell derived proteases. Loss of plasma from the vascular compartment may range from mild and transient to severe and prolonged, the latter often resulting in life threatening irreversible shock and death. Although there is a slightly higher risk (~10%) of developing classical DHF/DSS in persons experiencing secondary dengue infections, DHF/DSS may also occur in primary infections. This suggests that additional mechanisms of vascular pathogenesis exist that are not dependent on heterologous adaptive immune responses. Interestingly, DHF/DSS rarely or never occurs in the 3rd or 4th infection.

In vitro studies have shown that not all dengue viruses can be enhanced and that not all antibodies can enhance dengue infection. That, in addition to epidemiologic and virological studies showing that dengue viruses in nature vary greatly in their epidemic potential, and virulence (see Section “Genetics” above), raises the question as to whether dengue virus strains vary in their ability to stimulate the production of enhancing antibodies, whether this is associated with virulence, and, if so, how this relates to the immune enhancement hypothesis. Unfortunately, animal models cannot explain the disease mechanisms of different dengue strains in humans. However, accumulating sequence and field data suggest the dengue viruses, like most other animal

viruses, vary in their virulence and in their epidemic potential. As already noted, both host immunity and virus virulence are likely playing a role in the pathogenesis of severe dengue disease.

Patients infected with dengue viruses may also experience other forms of severe disease, including severe and uncontrolled bleeding, usually from the upper gastrointestinal (GI) tract. This severe hemorrhagic disease may be associated with multiple organ failure, and it is more difficult to manage than classical vascular leak syndrome. The underlying pathogenetic mechanism for this type of bleeding is not fully understood.

A third type of severe and fatal dengue infection, which may or may not involve overt hemorrhagic disease, is neurological symptoms. Although many patients with this syndrome present clinically as viral encephalitis, conclusive evidence that dengue viruses commonly infect the central nervous system has not yet been obtained. Available data suggests that neurological symptoms may be secondary to cerebral hemorrhage, edema, or other indirect effects of dengue virus infection.

Clinical Features of Infection

Dengue virus causes a spectrum of illness in humans ranging from subclinical to severe and fatal hemorrhagic disease with the latter representing only a small proportion of all infections. The incubation period may be as short as 3 days and as long as 14 days, but most often it is 4–7 days (Fig. 6). The majority of patients present with a mild, nonspecific febrile illness, or with classical dengue fever. The latter is generally observed in older children and adults, and is characterized by a sudden onset of fever, frontal headache, retro-ocular pain, and myalgias. Rash, joint pains, nausea and vomiting, lymphadenopathy and hemorrhagic manifestations such as nose and gum bleeding, purpura and petechiae are common (Fig. 5). The acute illness, which lasts for 3–7 days, is usually benign and self-limiting, but it can be very debilitating. Convalescence may be prolonged for several weeks.

As noted, severe dengue may present in several forms. The most common form of severe dengue is a vascular leak syndrome, often observed in children under 15 years of age, although this syndrome may also occur in adults in areas of lower endemicity. Severe dengue is characterized by acute onset of fever and a variety of nonspecific signs and symptoms that may last 2–7 days (Fig. 6). During this stage of illness, dengue is difficult to distinguish from many other viral, bacterial, and protozoal infections. In children, upper respiratory tract symptoms caused by concurrent infection with other viruses or bacteria are not uncommon. The differential diagnosis should include other hemorrhagic fevers, hepatitis, leptospirosis, typhoid, malaria, measles, influenza and other diseases causing fever.

The critical stage in severe dengue occurs when fever subsides to or below normal. This usually occurs 5–7 days after onset of fever (Fig. 6). Most patients recover without complications, but the patient's condition may deteriorate rapidly with signs of circulatory failure, neurological manifestations, shock and death, if proper management is not available. The main pathophysiological features of severe dengue involve immune system activation, increased microvascular permeability and plasma leakage into the extravascular spaces. There may be altered hemostasis involving thrombocytopenia, impaired coagulation and vascular dysfunction. Skin hemorrhages such as petechiae, easy bruising, bleeding at the sites of venipuncture, and purpura/ecchymosis are the most common hemorrhagic manifestations; GI hemorrhage may occur, usually after, but in some cases before, the onset of shock.

The World Health Organization (WHO) has recently redefined the definition of severe dengue. Previously limited to only DHF/DSS, other forms of severe disease not associated with vascular leakage are now included (Fig. 7). The strict criteria to define DHF remain unchanged with four major clinical manifestations: fever or recent history of fever, hemorrhagic manifestations, vascular leakage, and thrombocytopenia. Patients with DSS have DHF with objective signs of circulatory failure. Thrombocytopenia and hemoconcentration are constant features of DHF/DSS. As noted above, other severe forms of dengue include severe hemorrhage, myocardiopathy and neurological disease, which have been added to the new WHO guidelines. Patients may present with severe and uncontrollable upper GI bleeding with shock and death in the absence of hemoconcentration or other evidence of the vascular leak syndrome. Also, they may present with a variety of neurological and psychiatric disorders, including headache, dizziness, hysteria, and depression. In addition,

Fig. 6 A time course of dengue clinical symptoms during infection.

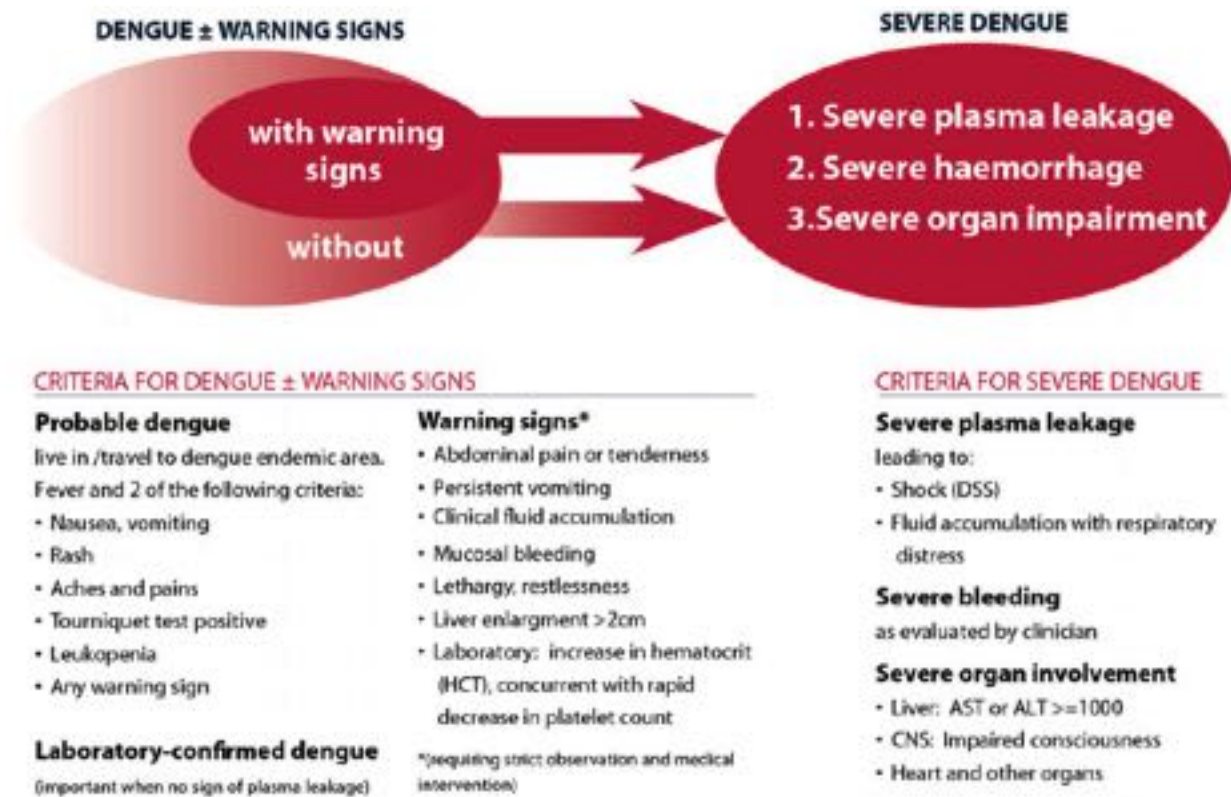

Fig. 7 Suggested dengue case classification and levels of severity; adapted from the 2009 WHO Dengue guidelines for diagnosis, treatment, prevention and control.

some patients present with clinical symptoms of viral encephalitis and Guillain-Barré syndrome, but as noted above, there is no conclusive evidence that CNS infection occurs.

Treatment of dengue infection is symptomatic since there are no specific antiviral drugs. Management of vascular leakage syndrome, however, is very effective with a corrective fluid replacement therapy. The prognosis of patients with DHF/DSS depends on early recognition, monitoring, and management of vascular leakage. Good nursing care is critical. A definitive diagnosis of dengue virus infection can only be made in the laboratory by serologic and/or virologic methods.

Pathology and Histopathology

The pathology of dengue virus infection is not well understood because systematic postmortem studies have not been done on patients representing all types and stages of severe dengue disease. The pathology may also be complicated by patient age, and co-morbidities. In general, the pathology of dengue is non-specific and difficult to distinguish from yellow fever, other viral hemorrhagic fevers, leptospirosis, and other diseases. Petechiae, serous effusion and organ hypoperfusion are common. Liver pathology is similar to that seen in yellow fever with centrilobular and mid-zonal necrosis, apoptosis and steatosis. There is often an increased proportion of immune cells seen in blood and in the spleen. Studies have not revealed destructive inflammatory vascular lesions, but some swelling and occasional necrosis has been observed in endothelial cells. Changes in the kidneys are suggestive of an immune complex type of glomerulonephritis. Complement deposition has also occasionally been identified in tissues. There is impaired bone marrow function, which improves when the patient becomes afebrile. Biopsy studies of the skin rash have demonstrated perivascular edema with infiltration of lymphocytes and monocytes.

Immune Response

Persons infected with dengue viruses produce IgM and IgG antibodies, both of which appear 5–7 days after onset of illness in primary infections. The highest titers of IgM antibodies are detected in primary dengue infections, but an IgM response is also detected in secondary and tertiary infections. The IgM response is transient and generally disappears 30–90 days after onset of illness in primary infections and after shorter periods of time in secondary and tertiary infections. IgG antibodies, in contrast, may persist for at least 60 years and probably throughout the life span of the patient. In persons experiencing their first dengue or

flavivirus infection, peak IgG levels are detected 14–21 days after onset of illness and seldom exceed titer values of 640–1280 as measured by hemagglutination-inhibition or neutralization tests. There are exceptions, however, with some infections inducing antibody titers typical of secondary or tertiary infections during primary infection. In secondary infections, there is a rapid anamnestic IgG immune response to dengue complex-and/or other flavivirus-specific antigenic determinants. Both IgM and IgG antibodies neutralize dengue viruses, and infection provides life-long immunity to the infecting virus serotype.

Both IgM and IgG antibodies to dengue viruses cross-react with other flavivirus antigens, including those of yellow fever, Japanese encephalitis, West Nile, Zika, and St. Louis encephalitis viruses. Those flavivirus cross-reactive antibodies are generally non-neutralizing. Cross-reactivity with viruses in the dengue complex makes the interpretation of serologic results difficult. In geographic areas where several flaviviruses are endemic, definitive laboratory diagnosis can only be made by virus isolation or nucleic acid detection, and in patients with a primary infection, by PRNT. Normally, a combination of laboratory (serologic and virologic), clinical, and epidemiologic data is used to confirm a diagnosis of dengue or other flavivirus infections.

Because dengue virus-specific IgG antibodies persist for many years or decades, their presence in a single serum sample is not diagnostic of current or recent infection. Lower IgG titers simply indicate that the person has had a previous infection at some time in the past. Paired serum samples are required to confirm a current infection by demonstrating a fourfold or greater rise in IgG antibody levels. The presence of detectable IgM antibody in a single serum sample is considered to be diagnostic for a recent infection because this isotype does not persist for long periods of time. Increasingly, NS1 protein is used as a diagnostic marker of acute dengue infection since this viral protein is secreted from infected cells and can be detected in patient serum. NS1, like RNA detection by PCR, is a surrogate marker for the presence of infectious virus.

Extensive work done in recent years has demonstrated that immunopathogenetic mechanisms play a major role in the pathophysiology of vascular leakage syndrome. Generally, CD4⁺ and CD8⁺ T-cell responses are directed against multiple viral proteins, including both structural and non-structural proteins. After primary infection, memory T cells proliferate in response to multiple dengue serotypes providing both specific and cross-reactive responses. After a secondary infection, T cell proliferation is of low-affinity and may be more reactive to the first infecting virus serotype than to the second virus strain, a phenomenon analogous to original antigenic sin seen in the antibody response. Whether T cell activation is involved in immune pathology is controversial and results from different human studies vary considerably. T cells have increasingly been suggested to contribute to infection control, both through the development of cytotoxic responses and through promoting high affinity antibody production. NK cells have also been identified to be activated during dengue infection; however, it is not yet clear whether they are primarily protective or potentially contribute to immune pathology.

The vascular leakage syndrome is commonly associated with a cascade of immunopathologic events in which increased infection of dendritic cells, macrophages and other cell types lead to a cytokine storm that is thought to increase vascular permeability. The literature supporting this hypothesis is extensive, but highly variable with many studies lacking controls or performed in immune compromised animals, where there is a potential of enhancing the role of virus replication in immune pathology or promoting infection in cell types that are normally resistant to infection. There is strong evidence, however, that pro- and anti-inflammatory cytokines are elevated during the acute febrile phase of the disease. Aside from cytokines, additional vasoactive inflammatory mediators and inhibitors of coagulation are released during an acute infection, including products such as mast cell proteases, heparin, and matrix metalloproteinases.

There is accumulating evidence that cell-mediated immunity also plays a role in terminating dengue infections. Dendritic cells (DCs) are likely the initial site of virus replication. Dengue virus infection stimulates DC maturation and activation, and the production of TNF- α , IFN- γ and IFN- α/β that are known to inhibit virus infection. DCs migrate to T-cell-rich lymphoid organs where T cells are activated, stimulating memory responses and releasing cytokines and chemokines. Transcriptional activation of DCs has been associated with asymptomatic infections, supporting the concept that T cell responses can be protective. During secondary infections, T cells may be specific for a previous infecting serotype of dengue and cross-reactive for the secondary serotype. In that situation, T-cell responses are likely to be dominated by a subset of memory T cells, which produce IFN- γ and CD40L, resulting in a better DC activation, T cell stimulatory capacity, IL-12 release, increased secretion of TNF- α and IFN- γ , as well as potentially altered cytokine responses. When viremia is cleared, the cascade of events initiated by a Th1 cytokine response in the absence of effective viral control may contribute to the pathogenesis of DHF. Cross-reactive CD8 T cells that have low affinity to the second infecting virus serotype (see above) may be ineffective in clearing viremia, thus permitting a higher virus load and a more severe disease. However, cross-reactive CD4 T cells may contribute to cross-protection by promoting germinal center responses and enhancing the kinetics of antibodies that can neutralize the secondary serotype.

Prevention and Control of Dengue

The options available for prevention and control of dengue have been limited, and dependent on controlling the mosquito vector, which has failed in most countries during the past 50 years. A highly effective vaccine against dengue is not available despite more than 70 years of research. However, recent progress in developing new mosquito control tools, vaccines and antiviral therapeutics has been promising, but it is unlikely that any single method or approach will be successful in reversing the trend of increased epidemic dengue. Most likely, a combination of vector control and vaccination will be needed to effectively control this disease.

Vaccines

Effective vaccination to prevent dengue will likely require a live attenuated vaccine since this strategy ensures induction of both T and B cell memory responses. One vaccine produced by Sanofi Pasteur under the name Dengvaxia, has been licensed for use in people 9–45 years of age in some countries. In clinical efficacy trials Dengvaxia has been shown to be effective in preventing severe disease by 93% and decreasing hospitalization by 81%. The vaccine is most effective in individuals who have previously been exposed to the virus. However, 6 year follow up of vaccinees showed that there is a small increased risk of severe disease and hospitalization in vaccinees who were dengue-naïve at the time of vaccination, leading WHO to recommend that it not be used in seronegative individuals. The WHO recommended pre-vaccination screening for serological evidence of previous dengue infection, but also suggested that Dengvaxia could be used in highly endemic areas with a seroprevalence of 80% or higher. Currently, it is uncertain whether or how Dengvaxia will be used in dengue control programs.

The dengue vaccine pipeline currently includes 2 candidate vaccines in phase 3 clinical trials, one in phase 2 and two in phase 1 (Table 1). In addition, there are several third generation vaccines under development using new molecular technology. The two most promising live attenuated candidate vaccines (CDC/Takeda and NIH/Merck) are expected to be licensed in the next 3–5 years. It is not known whether a balanced tetravalent protective response will be obtained. From a public health perspective, however, that may not be necessary. Current thinking is that a vaccine that protects against three or even two of the virus serotypes may be effective in protecting against a severe disease since 3rd and 4th infections are rarely if ever associated with a severe disease.

A very promising issue has also been the rapid progress in developing antiviral drugs and therapeutic antibodies that can be used in the treatment of dengue infection, and perhaps, even in prevention and control programs. Research is currently focused on developing a safe and inexpensive drug that inhibits dengue virus replication that can be used in a manner similar to influenza antivirals. While most effort has been directed towards developing a small molecule drug, many studies are now screening drugs that were developed against other viruses and that have proven to be safe in humans.

Monoclonal antibodies are also being developed for dengue therapeutics. Antibodies are able to limit virus infection through several known mechanisms including by aggregating virus particles, destabilizing the virus structure, preventing virus attachment to target cells, or by preventing fusion of the virus with the target cell membrane. Some monoclonal antibodies that are most effective in neutralizing DENV bind to the virus surface, locking the virus structure and preventing the dynamic movements required for virus attachment and fusion with the cell membrane. A DENV-1-specific therapeutic monoclonal antibody has shown promising results in early clinical trials and a DENV-2-specific antibody is being developed. These antibodies could be used for both treatment and for prophylaxis.

Currently, the most widely used way to prevent dengue infection is to control the mosquito vector that transmits the virus. Unfortunately, with the exception of Singapore, programs to control *A. aegypti* mosquitoes have not been successful. For more than 50 years, the recommended method to control mosquitoes has been spraying ultralow volume (ULV) or thermal fog application of insecticides to kill adult mosquitoes. Field trials in Puerto Rico, Jamaica, and Venezuela, however, showed that this method was not effective in significantly reducing natural mosquito populations for any length of time. This supports epidemiologic observations that space spraying has little or no impact on epidemic transmission of dengue viruses. Unfortunately, however, the method is still the most widely recommended.

Recent research has led to the development of a number of new and innovative chemical, genetic and biologic mosquito control tools. The insecticides include new classes of chemicals that will provide residual activity for 6 months to a year, a characteristic that is critical to control adult mosquitoes emerging from cryptic or hidden larval habitats. Other new insecticides can be formulated as spatial repellants to prevent mosquitoes from entering specific areas or to treat both natural and artificial oviposition sites. Both genetic and biological approaches to mosquito control are equally promising.

The most promising genetic approach is the release of sterile male mosquitoes into a natural population to mate with wild female mosquitoes. Male sterilization can be achieved by genetic modification, irradiation or biologically by Wolbachia infection. Sterile males can be produced by the millions and released as eggs, pupae or adults into natural populations. If the sterile males are released in high enough numbers, egg hatch rate will decrease and the wild mosquito population will be suppressed. Field trials have been conducted in Malaysia, Cayman Islands, Panama, Brazil, Singapore, the United States and China, all with promising results.

Table 1 The dengue vaccine pipeline by stage of clinical development

Company	Vaccine strategy	Development phase
Sanofi Pasteur	Chimeric, YF17-D backbone, DENV1–4	Licensed
NIH/Merck	LAV, DENV-1,-3 & -4, Δ30/31 + Chimeric, 2/4	Phase 3
CDC/Takeda	LAV, DENV2 PDK53; + Chimeric DENV1/2, 3/2 & 4/2	Phase 3
WRAIR/GSK	Inactivated, DENV1–4	Phase 2
NMRC	DNA, DENV1–4	Phase 1
Merck/Hawaii Biotech	Subunit, DENV1–4	Phase 1 (on hold)

A promising biological control tool is the infection of *A. aegypti* mosquitoes with a common bacterium, Wolbachia, that naturally infects over 70% of all insects in nature, but for reasons that are unknown, not *A. aegypti*. Several strains of Wolbachia have been adapted to infect *A. aegypti*, causing their decreased survival and decreased susceptibility to dengue, yellow fever, Zika and chikungunya viruses. Field trials have been carried out in Australia showing effective spread of Wolbachia into the natural *A. aegypti* populations and effective control of dengue in one city. Other trials in Vietnam, Indonesia, Brazil and Colombia are in progress.

An effective method of controlling *A. aegypti* is larval control, ie, to eliminate or control the larval habitats where the mosquitoes lay their eggs. Unfortunately, that is not possible in old cities that have expanded over the centuries and have many hidden or cryptic larval habitats. Fortunately, a number of these new mosquito control tools may be useful in reaching these sites, most of which are found in the domestic environment, where most transmission occurs. To have sustainability of prevention and control programs, some responsibility for mosquito control should be transferred from governments to citizens. For long-term sustainability, mosquito control programs must be regional, but operational control must be local, community-based and integrated. Persons living in *A. aegypti* infested communities have to be educated to take responsibility for their own health and help government agencies control vector mosquitoes, and thus prevent epidemic dengue. Effective sustainable prevention and control programs must involve a partnership between government agencies and the community.

Countries with endemic dengue should develop active, laboratory-based surveillance systems that can provide some degree of early warning for epidemic transmission. Finally, prevention of excess mortality associated with DHF/DSS can be achieved by educating physicians in endemic areas on clinical diagnosis and management of severe dengue. As demonstrated in countries such as Thailand, early recognition and proper clinical management are the key factors reducing DHF/DSS case-fatality rates.

Future

Continued population growth and urbanization of the tropical and subtropical areas, changing lifestyles, globalization and lack of effective mosquito control have been the most important factors responsible for the dramatically increased incidence and geographic expansion of dengue in the past 50 years. Epidemic dengue has become a global public health problem in the tropics and it is anticipated that this trend will continue unless more effective prevention and control strategies are developed and implemented worldwide. Fortunately, the dengue control pipeline includes a number of new and innovative tools, including vaccines, antiviral drugs, therapeutic antibodies, insecticides and other mosquito control tools, which if used in an integrated and synergistic way, could allow effective control of dengue in the near future.

This is an update of K.S. Brown, A. Silaghi, H. Feldmann, Ebolavirus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00662-2](https://doi.org/10.1016/B978-012374410-4.00662-2).

Classification

Ebola virus (EBOV) is the best known member of a relatively small but growing family of viruses known as *Filoviridae*, which itself belongs to the much larger order of negative-sense, single-stranded RNA viruses called *Mononegavirales* (Table 1). Within the family *Filoviridae* are five recognized genera—*Ebolavirus*, *Marburgvirus*, *Cuevavirus*, *Striavirus*, and *Thamnovirus*—each of which contains one or more species represented by specific type viruses. The genus *Ebolavirus* is composed of five species each with a single virus: *Zaire ebolavirus* (type virus: EBOV), *Sudan ebolavirus* (type virus: Sudan virus; SUDV), *Bundibugyo ebolavirus* (type virus: Bundibugyo virus; BDBV), *Tai Forest ebolavirus* (type virus: Tai Forest virus; TAFV), and *Reston ebolavirus* (type virus: Reston virus; RESTV). A sixth species of *Ebolavirus*, tentatively termed “*Bombali ebolavirus*” (type virus: Bombali virus; BOMV), and a sixth genus of *Filoviridae*, tentatively termed “*Dianlovirus*” (containing Mënglà virus; MLAV), have been proposed but have yet to be ratified by the International Committee on Taxonomy of Viruses. Informally, all viruses belonging to the *Filoviridae* family are referred to as filoviruses, while viruses belonging to the *Ebolavirus* genus are referred to as ebolaviruses.

Only ebolaviruses and marburgviruses are known to cause human disease, which is generally referred to as EBOV disease (EVD) or Marburg virus disease (MVD), replacing the outdated terms Ebola and Marburg hemorrhagic fever (EHF and MHF). Considering the severity of the diseases they cause, and the threat they pose to global public health, filoviruses, including EBOV, are considered Category A Bioterrorism Agents and Tier 1 Select Agents by the US Centers for Disease Control and Prevention and the Department of Health and Human Services, respectively. All work with filoviruses is therefore restricted to maximum containment (biosafety level 4; BSL-4) laboratories.

Epidemiology

Ebolaviruses were first identified in 1976 following two near-simultaneous outbreaks that occurred around Yambuku, Zaire (now the Democratic Republic of the Congo) and Nzara, Sudan (now South Sudan). Although these two outbreaks were originally attributed to a single virus—EBOV—years later it was determined that the etiological agent of the Sudanese outbreak was the highly related SUDV. Since then, four additional ebolaviruses have been discovered and dozens of outbreaks have occurred, mostly in Central Africa (Table 2). TAFV was discovered in 1994 following a single non-fatal infection in the Tai Forest reserve of Côte d'Ivoire, and BDBV was discovered in 2007 following an outbreak in the Bundibugyo region of Uganda. RESTV was first identified in 1989 in a group of fatally infected nonhuman primates (NHPs) that had been imported from the Philippines to Reston, Pennsylvania, and it appears to be apathogenic in humans. Recently, full genome sequences for a putative sixth ebolavirus, BOMV, have been identified in free-tailed bats from Sierra Leone, Guinea and Kenya, although, to date, infectious virus has not been isolated and no known human cases have been reported.

By far the largest and deadliest outbreak of any filovirus was that caused by EBOV in West Africa from 2013 to 2016. From a single index case in the village of Méliandou, Guinea, EBOV eventually spread throughout Western Africa to cause tens of thousands of cases. Guinea and the neighboring countries of Sierra Leone and Liberia bore the brunt of the epidemic, but several cases were exported to nearby African countries and numerous other countries around the world, including some European countries and the United States. Altogether the outbreak lasted nearly two and a half years and resulted in at least 28,616 cases and 11,310 deaths—although these numbers likely underestimate the true toll of the epidemic. In addition to the unprecedented number of human casualties, the West African EBOV epidemic also incited fear and anxiety around the world while at the same time devastating the public health infrastructure and economies of Guinea, Sierra Leone, and Liberia. Currently, the world's second largest filovirus outbreak—also caused by EBOV—is occurring in the North Kivu and Ituri provinces of the Democratic Republic of the Congo (DRC). At the time of writing, over 2000 deaths and 3000 cases have been recorded. Although these are obviously not the only outbreaks that have been caused by ebolaviruses, they are the worst, and they serve as a reminder of the ongoing threat posed by these viruses to global public health and biosecurity.

Ebolaviruses are considered to be zoonotic agents introduced into human populations either directly from the reservoir host or via intermediate hosts. The identity of this reservoir (or reservoirs) remains unknown; however, considerable circumstantial evidence suggests that this role may be fulfilled by bats. Antibodies specific to EBOV antigen, as well as EBOV-specific RNA sequences, have been identified in multiple species of bats (including *Hypsignathus monstrosus*, *Epomops franqueti*, and *Myonycteris torquata*), and epidemiological connections have been made between bats and index cases for certain outbreaks. Moreover, the complete genome of BOMV was isolated from bats (*Chaerephon pumilus* and *Mops condylurus*), and extensive lines of evidence

Fig. 1 Ebola Virus Genome Structure and Morphology. The Ebola virus (EBOV) genome is a single-stranded, negative sense RNA molecule, approximately 19 kb in length. The genome consists of seven genes, each indicated by a coloured box: nucleoprotein (NP), virion protein 35 (VP35), VP40, glycoprotein (GP), VP30, and the RNA-dependent RNA polymerase (L). Transcriptional editing of the GP gene at a conserved editing site (indicated by an arrow) produces two additional transcripts: soluble GP (sGP) and small soluble GP (ssGP). The grey regions of the diagram represent the 3' and 5' leader and trailer regions, respectively, as well as the untranslated and intergenic regions. Gene overlaps are indicated by arrows. A scanning electron microscope image depicts an EBOV virion, highlighted in yellow. A schematic depicts the structural proteins (NP, VP35, VP40, GP, VP30, VP24, and L), as well as the viral genome, that comprise the distinct, filamentous morphology of the virion.

suggest that the Egyptian rousette bat (*Rousettus aegypticus*) serves as a definitive reservoir for the related marburgviruses. Serological evidence of SUDV, TAFV, BDBV, and RESTV has also been reported in bats, although it is possible that cross-reactivity may complicate the specificity of these results. NHPs, such as gorillas and chimpanzees, along with other animals, such as duikers, are likely important dead end hosts. NHPs, in particular, are highly susceptible to ebolavirus infection and are common sources of bushmeat, the butchering and consumption of which has been linked to virus spillover into human populations.

The majority of ebolavirus outbreaks appear to cluster in distinct environments depending on the viral species, suggesting that different ebolaviruses occupy distinct ecological niches, a hypothesis that is supported by mathematical modeling. Moreover, the relatively low genetic diversity among different ebolaviruses provides further evidence suggesting strong ecological adaptation. Interestingly, although all human-pathogenic ebolaviruses (EBOV, SUDV, TAFV, BDBV) seem to exist near equatorial Africa, RESTV is found in the Philippines, suggesting that ebolaviruses may be more widely distributed than is currently appreciated. Indeed, serological studies have found evidence of ebolaviruses in Bangladesh and China, Lloviu virus (the sole member of the *Cuevavirus* genus) was identified in bats from Spain, and Mënglà virus (genus "*Dianlovirus*") was discovered in bats from Southern China. Ultimately, however, since the geographic distribution of ebolaviruses is directly related to the reservoir species, a complete understanding of ebolavirus epidemiology awaits the definitive identification of the reservoir host or hosts.

Genome

The EBOV genome, like that of all ebolaviruses, comprises a single, linear strand of negative sense RNA approximately 19 kb in length (Fig. 1). The genome contains seven genes, each of which encodes one of seven structural proteins: the nucleoprotein (NP), the 35-kDa virion protein (VP35), VP40, the glycoprotein (GP), VP30, VP24, and the RNA-dependent RNA polymerase "Large" protein (L) (Table 3). As a result of transcriptional editing, the GP gene also encodes two non-structural proteins: soluble GP (sGP) and small soluble GP (ssGP). A small 40 amino acid peptide, known as Δ -peptide is also generated by a post-translational cleavage of sGP (Table 3). Each gene is flanked at its 3' and 5' end by highly conserved untranslated regions (UTRs), which contain transcription start (3'-CUnCnUnUAAUU-5') and stop (3'-UAAUUCUUUUU-5') signals, respectively, and incorporate a conserved pentamer (UAAUU). For all ebolaviruses except RESTV, three intergenic regions of variable length exist between NP/VP35, VP40/GP, and VP30/VP24, while three small gene overlaps (where the start site of one gene occurs prior to the stop site of the preceding gene) exist between VP35/VP40, GP/VP30, and VP24/L. Conversely, RESTV lacks the gene overlap between GP and VP30. The genome itself is flanked by a conserved 3' leader sequence, approximately 60 base pairs in length, and 5' trailer sequence, which varies in length depending on the virus, ranging from as little as 25 bp in RESTV to as long as 676 bp in EBOV. The leader and trailer sequences, which possess a high degree of complementarity and are thought to form secondary structures, contain

Table 3 Major defined roles of ebolavirus proteins

	<i>Structural</i>	<i>Transcription/Replication</i>	<i>Immunomodulatory</i>
NP	Major component of the nucleocapsid; binds and protects viral genome RNA	Critical component of the viral polymerase complex	Not known
VP35	Critical component of the nucleocapsid	Polymerase cofactor; critical component of the viral polymerase complex	Binds and sequesters dsRNA; inhibits type I IFN gene expression
VP40	Major matrix protein; critical for virion assembly and budding	Negative regulator of transcription/replication	Not known
GP _{1,2}	Critical component of virion; required for virus attachment and fusion		Inhibits tetherin activity
sGP			Antibody decoy
Δ-peptide			Not known
ssGP			Not known
VP30	Component of the nucleocapsid	Critical transcription factor	Not known
VP24	Critical component of the nucleocapsid	Negative regulator of transcription/replication	Inhibits IFN gene expression and signaling
L	Component of the nucleocapsid	RNA-dependent RNA polymerase	Not known

conserved signals critical for genome replication and transcription. Importantly, because the genome of ebolaviruses—like all filoviruses, and, indeed, all mononegaviruses—is negative sense and therefore complementary to the mRNA sequences, it is not infectious. The viral polymerase complex is thus required to initiate replication and production of the (positive sense) antigenome prior to mRNA transcription.

Overall, the genomes of viruses from different species within the *Ebolavirus* genus differ from each other, on the nucleotide level, by approximately 23%–36% while the genomes of ebolaviruses differ from those of other filoviruses by greater than 50%. For the most part, these differences are recapitulated at the level of the GP gene, and highlight the diversity within the *Filoviridae* family (Fig. 2). Intriguingly, however, within a given species of *Ebolavirus*, different variants are highly conserved, typically displaying less than 5% divergence.

Virion Structure

Filoviruses derive their name from the Latin word *filum*, meaning “thread”, which accurately describes the overall morphology of the virion (Fig. 1). Ebolavirus virions, like those of all filoviruses, are long, filamentous particles that are often linear but can also bend into U-shaped, comma-shaped, or toroidal structures, indicating a high-degree of structural flexibility. Despite this flexibility, the EBOV virion maintains a uniform diameter of 96 nm, as measured from opposing outer edges of the viral envelope, and the length of a particle containing a single genome is approximately 980 nm long. However, approximately half of EBOV virions are polyploid, in which a single virion contains more than one copy of the viral genome, each arranged end-to-end continuously or separated from one another by a small gap. The result of this polyploidy is a population of exceptionally long virus particles of varying length, with some particles observed to contain as many as 22 genomes and measure over 21 μm in length. Empty virions containing no viral genome are also observed, possessing much smaller diameters (48–52 nm) and random lengths. Branched filaments are frequently observed in tissue culture supernatants, although the branches are typically empty.

Virion morphology is ultimately determined by the seven ebolavirus structural proteins, most of which compose some part of the helical nucleocapsid (Fig. 1). Indeed, the EBOV nucleocapsid is among the most complex of all mononegaviruses and consists of the virus genome in complex with five viral proteins: NP, VP35, VP24, VP30, and L. NP binds directly to genomic RNA in a sequence-independent manner and oligomerizes to form a left-handed helical, loosely-coiled structure that is then more tightly condensed via interactions with VP24 and VP35, which are thought to form a heterodimeric “bridge” along the outer edge of the helix. Although NP appears to form vertical contacts along the inner edge of the helix with neighboring NP monomers on adjacent helical layers, no such connections are apparent along the outer edge of the helix, thus permitting the nucleocapsid’s characteristic flexibility. Overall, the nucleocapsid has an inner-edge diameter of ~22 nm, an outer-edge diameter of ~41 nm, and a pitch of ~7 nm with 10.8 NP units per helical turn. Analysis of virion protein contents suggests that NP, VP35, VP24, and VP30 are all present at equimolar ratios, which is consistent with their involvement in forming repeating units of a highly ordered nucleocapsid. The role that VP30 plays in this structure remains unclear, however, since its presence or absence does not appear to affect nucleocapsid morphology. Likewise, although L is also considered to be a part of the nucleocapsid, it is present at such low copy numbers that it is unlikely to play a major structural role. VP40, the membrane-associated matrix protein, is not a part of the viral nucleocapsid, but instead serves to simultaneously drive the budding of nascent virions from the plasma membrane of the host cell and recruit nucleocapsids to the site of budding. In the virion, a layer of VP40 approximately 9 nm thick is thought to underlie the viral envelope, and VP40 extensions from this layer are thought to bridge the gap between the envelope and the nucleocapsid. In this way, VP40 keeps the nucleocapsid centered in the virion, with a spacing of 7–8 nm between the nucleocapsid and the

Fig. 2 *Representative Filovirus Phylogeny.* GP nucleotide sequences were aligned using MUSCLE, and a Neighbor-Joining phylogenetic tree was generated using Geneious Tree Builder. Percent consensus support is indicated at each branch, which was bootstrapped 1000 times. Genbank Accession Numbers: BDBV variant Butalya, KR063673.1; TAFV, KU182910.1; EBOV variant Mayinga, AF086833.2; BOMV, MF319185.1; SUDV variant Boniface, MH121162.1; RESTV variant Pennsylvania, AF522874.1; LLOV, NC_016144.1; MLAV, KX371887.2; MARV variant Angola, KU978782.1; RAVV, KU179482.1.

envelope. The outer surface of the viral envelope is studded with the heavily glycosylated viral glycoprotein (GP_{1,2}), the virus's only transmembrane surface protein and the sole structure responsible for receptor-mediated entry into host cells. GP_{1,2}, a class I fusion protein ~13 nm in length, is composed of a trimer of three identical disulfide-bound dimers consisting of proteins GP1 and GP2, which mediate receptor binding and membrane fusion, respectively.

Replication Cycle

Virus Attachment and Fusion

The virus replication cycle begins with virion attachment to a host cell (Fig. 3). Although ebolaviruses are thought to preferentially infect dendritic cells and macrophages early following infection, they have a broad cell and tissue tropism overall. Accordingly, with a notable exception of lymphocytes, ebolaviruses are capable of infecting many different cell types, including fibroblasts, epithelial and endothelial cells, and hepatocytes. Attachment to a host cell is mediated by at least two distinct mechanisms: (1) carbohydrate-binding receptors on the cell surface interacting with the heavily glycosylated GP_{1,2} and (2) phosphatidylserine (PS) receptors interacting with PS in the viral envelope. It is thought that the N- and O-linked glycans on GP_{1,2} interact promiscuously and non-specifically with a variety of carbohydrate-binding receptors, including C-type lectin receptors (such as DC-SIGN, L-SIGN, and LSECtin) and glycosaminoglycans, but that additional interactions between PS and PS receptors, such as those in the TIM (T-cell, immunoglobulin, mucin domain receptor) and TAM (Tyro3, Axl, Mer) families, are necessary for virus internalization. The broad distribution and redundancy of these attachment factors likely helps to explain the equally broad cell and tissue tropism

Fig. 3 The Ebola Virus Replication Cycle. Virion attachment to the host cell is mediated in part by non-specific interactions between EBOV GP and a number of different carbohydrate-binding factors, although interactions between phosphatidylserine in the virion envelope and phosphatidylserine receptors in the cell membrane also facilitate attachment. Following attachment, the virion is internalized by micropinocytosis, after which fusion between the viral and cellular envelopes is mediated by GP and Niemann-Pick C1 (NPC1), the cellular entry receptor for the virus. Primary transcription occurs following release of the NP-encapsidated viral genomic RNA into the cytoplasm and is mediated by the viral ribonucleoprotein complex (RNP) consisting of L, VP35, VP30. Host cell machinery translates the mRNA into protein. NP-encapsidated genome serves as a template for genome replication, carried out by L and VP35, via a positive-sense antigenomic intermediate. NP-encapsidated genomes are further encapsidated by VP35, VP24, VP30, and L, to generate highly ordered helical nucleocapsids that are trafficked to the cell membrane, where VP40 drives virus budding.

exhibited by ebolaviruses, and it also explains why a single surface-expressed cellular protein has yet to be identified as indispensable for virus entry.

Following attachment, virions are thought to be internalized primarily via macropinocytosis, although other cellular uptake pathways may play a role, depending on cell type and the attachment factors engaged (Fig. 3). The internalized virion is then trafficked through the progressively-acidic endocytic pathway where cleavage by the cysteine proteases cathepsin L and B removes the GP_{1,2} mucin-like domain and glycan cap, exposes the receptor binding site, and prepares the molecule for fusion-dependent conformational changes.

The cellular entry receptor for ebolaviruses was identified to be Niemann-Pick C1 (NPC1), a large, highly-conserved protein involved in cholesterol transport that is ubiquitously expressed and located on the interior membrane of late endosomes. NPC1 is critical for ebolavirus entry, and cells lacking this molecule are resistant to infection. Likewise, transgenic mice lacking the *Npc1* gene are resistant to infection. Proteolytically cleaved GP_{1,2} binds to domain C of NPC1 via the exposed receptor binding site, and through a process that is still incompletely defined, a series of conformational changes are thought to occur in GP_{1,2} that release the internal fusion loop and lead to fusion between the virion and endosomal membranes. In addition to the requirement for NPC1, the acidic environment of the late endosome/early lysosome is also required for fusion, and additional but unidentified endosomal factors may also be required. Ultimately, fusion of the virion and endosomal membranes releases the viral nucleocapsid into the cytoplasm, from where primary transcription commences.

Primary Transcription & Translation

Because the viral genome is in the negative sense and cannot be directly translated into protein, positive sense viral mRNAs must first be transcribed from the genome before the remainder of the replication cycle can take place (Fig. 3). The viral polymerase L binds to a conserved promoter in the 3' (Leader) end of the NP-encapsidated genome and moves successively towards the 5' end, initiating and terminating transcription at each gene's transcriptional start and stop sites, respectively. Newly transcribed viral mRNAs are capped by the viral polymerase and polyadenylated by a polymerase stuttering mechanism at the transcription start site. mRNAs are monocistronic and, unlike the virus genome, are not encapsidated by NP. Because a certain proportion of the polymerase falls off the genome at each transcription stop site, the probability of the polymerase transcribing a given gene decreases with the gene's distance from the 3' end of the genome. This results in a gradient of mRNA concentrations, with transcripts for NP being the most abundant and transcripts for L being the least abundant. Importantly, VP35 is an essential—but non-enzymatic—cofactor for the viral

polymerase that is thought to connect L to the NP-encapsidated genome by interacting with both proteins. VP30 is also required for transcription, particularly for activation of transcription from the leader sequence and re-initiation from each gene's transcription start sites, and its function depends heavily on its phosphorylation state. Along with L, NP, and the virus genome, these components form the ribonucleoprotein complex (RNP), and they are necessary and sufficient for ebolavirus transcription. Subsequent translation of viral mRNAs is completed by host cellular machinery and is thought to occur at distinct sites within the host cell.

One key feature of ebolavirus transcription that distinguishes it from that of the marburgviruses, is the use of co-transcriptional editing to produce multiple products from the *GP* gene. The primary product of the *GP* gene is the soluble glycoprotein (sGP), which is produced when the translational machinery encounters a stop codon roughly in the middle of the gene. Post-translational cleavage of sGP at its C-terminus produces the Δ -peptide, and both products are secreted from the infected cell. Thanks to a stretch of uridine residues before the stop codon, however, the viral polymerase occasionally stutters during transcription, resulting in the addition of a non-templated adenosine residue added to the mRNA. This additional residue results in a frameshift that allows translation to continue along the second half of the *GP* transcript, producing the pre-cursor protein to GP_{1,2}. Post-translational cleavage of this protein by furin-like proteases produces the GP1 and GP2 subunits, which then dimerize and trimerize to form the functional GP_{1,2}. Interestingly, the addition of two adenosine residues to the *GP* mRNA results in a different frameshift that creates a third stop codon ahead of the first two, thus producing the small soluble glycoprotein (ssGP). Like sGP and Δ -peptide, ssGP is also secreted from the cell. The function of these three products has yet to be clearly elucidated.

Replication

As transcription and translation continue, increasing levels of viral protein—including NP and VP30—are thought to trigger the switch to replication, although the details remain unclear. While dephosphorylated VP30 is required for the transcriptional activity of the RNP complex, phosphorylation of VP30 causes its dissociation from the RNP complex and shifts RNA synthesis towards replication. NP-encapsidated genome also serves as a template for viral RNA replication, which requires L and VP35. The polymerase complex binds to a bipartite replication promoter in the leader sequence of the genome and synthesizes a complementary positive-sense genome, referred to as the antigenome, which is immediately encapsidated by NP (**Fig. 3**). The antigenome then serves as a replication intermediate for the synthesis of additional copies of the viral genome. EBOV replication has been demonstrated to occur within peri-nuclear viral inclusion bodies, which appear to be dynamic and complex aggregates of viral proteins and RNA. Some evidence exists for the involvement of cellular proteins in replication/transcription, but further research is required.

Assembly & Budding

Although the structure of the mature viral nucleocapsid has been well studied, the dynamics of assembly are incompletely understood. Following transcription and replication, the NP-encapsidated viral genomes are further encapsidated by VP35, VP24, VP30, and L, which together generate the highly ordered, helical nucleocapsid described above (**Fig. 3**). Based on the ability of VP24 to inhibit transcription and replication in *in vitro* experimental systems, it has been proposed that the addition of VP24 to the nascent nucleocapsid represents the final step in nucleocapsid assembly, serving to condense the structure and restrict access to the genome by the viral replication machinery.

Mature nucleocapsids must then travel from the perinuclear region in which they are assembled to the plasma membrane, from where virus budding occurs. VP40, the matrix protein, is thought to be transported through the retrograde late endosomal pathway or in association with COPII vesicles to the underside of the plasma membrane, where it exists as a higher-order oligomer. Similarly, GP_{1,2} is transported to the plasma membrane via the ER-Golgi secretory pathway and collects in areas rich in VP40, likely due to interactions between the GP_{1,2} cytoplasmic domain and VP40. Actin-dependent transport mechanisms are thought to propel EBOV nucleocapsids along their long axis towards these sites on the plasma membrane, where interactions between NP and VP40 facilitate the envelopment of the nucleocapsid. Budding of the nascent virion from the cell is thought to require, at least in part, components of the endosomal sorting complex required for transport (ESCRT), which interact with two overlapping late domains present in VP40. Additional mechanisms may also be involved in virus budding, and the potential for direct cell-to-cell transmission remains a relatively under-investigated possibility.

Immune Evasion

The successful completion of the virus replication cycle, and the subsequent dissemination of infection, relies on the ability of the virus to evade the host's immune defences. Two of the most critical ebolavirus immunomodulatory proteins are VP35 and VP24. In addition to its roles in virion structure and transcription/replication, VP35 also functions to inhibit the induction of a type I interferon (IFN) response by binding to and sequestering double-stranded RNA (dsRNA) from intracellular nucleic acid receptors, such as RIG-I. Moreover, direct interactions between VP35 and components of the IFN-signaling cascade, including IKK ϵ , TBK1 and IRF7, also serve to limit the induction of the IFN response. VP24, on the other hand, binds to members of the NFI-1 subfamily of karyopherin- α proteins and prevents their translocation of STAT1 into the nucleus. Since STAT1 nuclear translocation is a critical step in the induction of IFN-stimulated genes (ISGs), VP24 effectively blunts the antiviral response triggered by type I IFN signaling. VP24 has also been shown to inhibit RIG-I-dependent IFN gene expression. GP_{1,2} also plays a role at the plasma

membrane in preventing the activity of tetherin, a viral restriction factor that interferes with virus budding, and sGP, may serve as a decoy molecule for the antibody response. Given the multi-functional nature of most ebolavirus proteins, additional immunomodulatory activities of other proteins likely exist, although further investigation is required.

Clinical Features

Prior to the West African epidemic, there was limited data available characterizing EVD, and, as a result, much of what we understood about this disease was obtained from animal models, usually in the context of EBOV infection. Different animal species, such as mice, guinea pigs, hamsters, ferrets, and NHPs have been used to model EVD and evaluate countermeasures—and each animal has its own set of advantages and disadvantages. Although inexpensive and widely accessible, immune-competent rodents are inherently resistant to EBOV infection, and virus must therefore be adapted through serial passaging in these animals to produce a lethal disease. Conversely, ferrets and NHPs are susceptible to wild type EBOV and exhibit disease remarkably similar to what is observed in humans. Rhesus and cynomolgus macaques, in particular, display a majority of the clinical signs of human disease, and they are considered the gold-standard model for research. Indeed, much of what is understood about EVD in humans was originally described in the NHP infection model. Our current understanding of human EVD is based predominantly on what we have learned from the West African EBOV epidemic, which infected more people than all previous EBOV outbreaks combined and produced a survivor cohort of thousands of people.

Early Disease

Like many other infectious diseases, the early stages of EVD include an asymptomatic incubation period followed by the onset of nonspecific signs of disease. These symptoms include fatigue, malaise and myalgia often coinciding with the onset of fever. Because these symptoms are not specific for EVD, the disease can be mistaken for other, more prevalent diseases in Africa, such as malaria, yellow fever, and Dengue. Although diagnosis of EVD in this early stage may be possible, it remains realistic, since the early symptoms precede the detectable presence of virus and viral RNA in the blood.

Peak Disease

Within the first week of illness, EVD patients become progressively weaker and develop nausea, vomiting, and diarrhea. Some cases also develop a maculo-papular rash and oozing from venipuncture sites or mucosal membranes. During this time, patients develop disseminated intravascular coagulation (DIC) along with thrombocytopenia. Patients are also extremely infectious, and the virus is present in all body fluids. If patients are not properly rehydrated at this point, loss of fluid from diarrhea and vascular leakage can result in severe dehydration and hypovolemic shock, ultimately leading to organ failure and death. Since EBOV replicates systemically during peak illness, almost all organs are affected. Liver damage is documented by an increase in liver enzyme levels, and an increase in creatinine levels is indicative of an acute kidney injury and subsequent renal failure. Viral antigens can be found systemically but is most abundant in the liver and spleen. In many EVD cases, central nervous system (CNS) dysfunction and life-threatening meningoencephalitis are observed.

Recovery

The survival of EVD is associated with a decline in viremia and the development of a life-saving adaptive immune response towards the end of peak disease. However, EVD survivors can develop sequelae, as documented in limited reports from previous outbreaks. The EVD epidemic in West Africa resulted in the largest cohort of EVD survivors to date, and many have been followed to document late-onset sequelae. The most commonly reported sequela is uveitis, which occurs in ~20% of EVD survivors and results in light sensitivity as well as blurred vision or temporary loss of vision. Other sequelae include hepatitis, myelitis, tinnitus, difficulty hearing and temporary hearing loss, cognitive difficulties, fatigue, muscle pain, and general weakness. These symptoms have been described to persist for one year or longer.

Virus Persistence

Until the epidemic in West Africa, EBOV persistence had only been anecdotally described from the outbreak in Kikwit, DRC in 1995. Now, there is increasing evidence that EBOV persists in immune-protected sites and can cause late manifestations of disease months and years after initial infection. Indeed, infectious EBOV has been isolated from the eyes, CNS, and male reproductive organs (mainly the testes) from EVD survivors. During the epidemic, there were a couple examples of sexual transmission of EBOV originating from male EVD survivors. These events were discovered and documented based on EBOV sequence data. There is limited data available on what triggers the reactivation of EBOV from immune-protected sites and causes a disease; however, this topic is the focus of ongoing research, and several animal models are being used to model and analyze this phenomenon.

Fig. 4 *Ebola Virus Pathogenesis.* The primary target cells of Ebola virus infection are thought to be monocytes, macrophages, and dendritic cells. Infection of these cells not only permits virus dissemination, but also affects the immune response to infection, resulting in the production of inflammatory chemokines and cytokines as well as the impairment of maturation and lymphocyte co-stimulation. Immune dysfunction exacerbates virus dissemination and, along with rampant virus replication, contributes to organ damage. Damage to the adrenal cortex contributes to hypotension and hypovolemia, while damage to the liver contributes to coagulation dysfunction that, along with vascular dysfunction, can produce hemorrhage. Ultimately, death is precipitated by multi-organ failure and hypovolemic shock.

Pathogenesis

Most of the information available regarding EBOV pathogenicity is derived from infections in animal models, as well as human cases from the West African epidemic. Fatal EVD cases appear to be the result of systemic shock due to vascular dysfunction and leakage, which is caused by a complex interaction of the immune system with vascular physiology. There are three major processes that are thought to lead to hypovolemic shock and death: (1) increased vascular permeability; (2) DIC; and (3) impaired protective immune responses. The first two processes result from a series of events starting with the infection of primary target cells, namely monocytes, macrophages and dendritic cells (Fig. 4).

Infected macrophages are strongly activated—secreting pro-inflammatory molecules such as interleukin 6 (IL-6), tumor necrosis factor alpha (TNF)- α , IL-1 β , nitric oxide (NO)—and serve to spread the infection systemically. In contrast, infection of dendritic cells results in their impaired activation, with no upregulation of co-stimulatory molecules, such as MHC class I and II molecules, CD80, CD86, and CD40. Activation of endothelial cells by inflammatory mediators such as TNF- α and NO is believed to be the main cause for the decrease in their barrier function. TNF- α , NO, and pro-inflammatory cytokines increase vascular permeability and the expression of adhesion molecules on the surface of endothelial cells, which are necessary in extravasation of immune cells in inflamed tissue. Although these pro-inflammatory cytokines are an integral part of a normal, localized immune response by attracting and activating immune cells to the site of infection, in the context of a systemic and extensive response, they have a negative effect by inducing shock. Endothelial cells also serve as target cells for EBOV, and infection results in their activation—as indicated by the upregulation of adhesion molecule expression followed by cytolysis. However, the destruction of endothelial cells in vivo can only be observed at the end stage of the disease.

Infection of macrophages also results in the expression of tissue factor (TF), which can impair the anticoagulant protein-C pathway by downmodulating thrombomodulin. TF is believed to be an important protein in the development of DIC, since

inhibition of TF delays death in NHPs and offers limited protection. TNF- α can also induce TF expression in endothelial cells, thus amplifying coagulopathy and DIC. Moreover, coagulopathy is known to enhance inflammation, leading to a vicious cycle where inflammation enhances coagulopathy, which in turn amplifies inflammation. Rapid systemic viral replication is also an integral part of EVD pathogenesis. EBOV infection in humans and NHPs results in rapid massive viremia and high titers in many organs, especially in the spleen and liver. This correlates with an impaired innate and adaptive immune response.

Interestingly, high viremia and lethality are only seen in mice if a host-adapted virus or immune-deficient animals are used. These observations suggest that evasion of immune responses plays a pivotal role in pathogenesis. Indeed, mice lacking the interferon (IFN) α/β receptor or STAT1, the main signaling molecule in response to type I IFN, are extremely susceptible to EBOV infection and develop a lethal disease. Moreover, mouse-adapted (MA)-EBOV is less sensitive to IFN- α treatment in murine macrophages compared to wild type EBOV, and analysis of genomic mutations in MA-EBOV indicated that mutations in NP and VP24 are sufficient for a lethal phenotype. Although VP24 inhibits the interferon response in vitro, it remains unclear whether the mutations in MA-EBOV are required for type I IFN evasion or other functions. Nevertheless, while treatment of NHPs with IFN- α does not protect the animals, it does delay death, suggesting that the type I IFN response may be central to EBOV pathogenesis. EBOV is also able to inhibit IFN production through VP35, and deletion/mutation of the region in VP35 involved in its IFN antagonism results in a highly attenuated virus that does not cause disease in NHPs. Furthermore, comparative in vitro gene microarray analysis demonstrated a correlation between cytotoxicity and IFN antagonism, which was strongest with EBOV and weakest with RESTV.

Adaptive immune responses are also impaired during infection. As mentioned above, upregulation of co-stimulatory molecules is inhibited in dendritic cells, which reduces activation of T cells. There is also a dramatic reduction in the number of T and natural killer cells, despite the fact that lymphocytes do not support EBOV replication. It is believed that lymphopenia is caused by “bystander” apoptosis, although the mechanism is not well understood.

Diagnosis

Diagnosing EBOV infections in humans is difficult early on as the disease presents with symptoms common to many other infectious diseases. EBOV particles (viral antigens and viral RNA) and IgM antibodies specific to EBOV proteins are among the first parameters that can be detected in blood and serum samples generally at the same time as symptom onset. In the early outbreaks in Zaire (now DRC), Sudan and Gabon samples were shipped to Europe and the USA where antibodies were detected by ELISA and immunofluorescence; in addition, virus isolation was attempted. During the Kikwit, DRC outbreak in 1995, antigen detection was performed, and EBOV RNA was identified via conventional reverse transcription polymerase chain reaction (RT-PCR). The US CDC used both assays afterwards with good success in the field laboratories in rural areas. In the early 2000s, real-time RT-PCR assays using fluorescent probes were designed for the detection of EBOV from patient samples. Eventually, the real-time RT-PCR tests replaced all other tests since the application is manageable in the field, with a turn-around time of ~2–3 h from the sample receipt to a test result. Several laboratory-developed and commercial tests are currently being used, but only limited data is available regarding their specificity and sensitivity. These tests have also been developed to work on automated diagnostic systems for high-throughput capacity.

Other tests with a fast turn-around time include antibody-based lateral flow immunoassays designed for the detection of EBOV VP40 antigen or a combination of VP40, NP and GP antigens. Limited data is available regarding the sensitivity and specificity of these assays, and more testing is needed.

Treatment

Monoclonal Antibody Therapy

Shortly after the discovery of EBOV and SUDV, scientists started to develop potential treatment strategies. Convalescent serum therapy was among the first to be tested in animal models, but it demonstrated limited efficacy and was not developed further. However, during the EBOV outbreak in Kikwit, DRC in 1995 the treatment was used with a questionable success. Similarly, EBOV-specific equine IgG treatment was evaluated in NHPs with limited success. Despite these early setbacks, the scientific community continued to pursue antibody-based therapeutics. The human-derived monoclonal antibody KZ52 was tested in rodents with good efficacy but failed to protect NHPs from a lethal disease.

In 2012 it was demonstrated that purified EBOV-specific IgG from NHPs could protect naïve NHPs from a lethal disease when multiple doses were administered even after infection. Based on this report significant efforts were made to develop poly- and monoclonal antibody therapies. Two antibody cocktails, MB-003 and ZMAb, each consisting of three monoclonal antibodies, were developed approximately the same time. MB-003 used plant-produced human-mouse chimeric antibodies, whereas ZMAb comprised a mixture of mouse monoclonal antibodies. Three doses of each cocktail protected NHPs from the lethal disease depending on antibody amount and time of administration. Notably, a cocktail composed of two ZMAb antibodies and one MB-003 antibody resulted in what is now known as ZMapp and provided superior efficacy in NHPs. In 2014, during the West African epidemic, ZMapp was administered to two patients repatriated to the USA after they fell ill from EVD in Liberia, and it was

subsequently used on at least four additional patients evacuated from West Africa. ZMapp was also tested in phase 3 clinical trials towards the end of the West African outbreak, where it showed benefit compared to the standard care alone, although the results were not significant. More recently, a next-generation cocktail of three human antibodies, known as REGN-EB3, and a single human-derived monoclonal antibody, known as mAb114, have shown promising protective efficacy in NHPs. All three monoclonal antibody therapies are currently being used in clinical trials in the ongoing outbreak in the DRC, with an initial report showing superior efficacy and higher survival rates following a single intravenous dose of mAb114 or REGN-EB3 compared to three intravenous doses of ZMapp.

Besides antibody therapeutics, other approaches have also been tried to counter EVD, including small interfering RNAs (siRNAs), phosphorodiamidate morpholino oligomers (PMOs), small-molecule compounds, immunomodulatory approaches, and post-exposure vaccination. The most successful ones are explained in detail below.

Small Interfering RNAs (siRNAs)

The treatment potential of siRNAs against EBOV infection in NHPs was first described in 2010 when four intravenous doses of a cocktail of three siRNAs targeting VP24, VP35 and L packaged in a lipid nanoparticle protected animal from a lethal disease. The cocktail was further modified to contain siRNAs targeting L and VP35 and was termed TKM-Ebola. TKM-Ebola was administered to EVD patients evacuated from West Africa in 2014; however, because these patients received other care in addition to the siRNA, it was unclear whether the treatment was beneficial. The siRNA sequences were subsequently modified to match the outbreak strain (EBOV variant Makona), and this new product, now termed TKM-130803, was uniformly protective when seven doses were administered intravenously to EBOV-Makona-infected NHPs. In 2015, a small phase 2 clinical trial of TKM-130803 was conducted in Sierra Leone. Twelve patients received treatment, but only three individuals received the full seven doses and survived. Disease was too far advanced in the other nine patients, all of whom died before the remaining doses could be administered.

Small-Molecule Compounds

Favipiravir, also known as T-705, has broad antiviral activity against a number of RNA viruses. It has shown partial protective efficacy in preclinical NHP studies against EBOV when administered intravenously twice daily for 14 days starting two days before a lethal EBOV infection. Treatment success was dependent on the dose, with the highest dose resulting in 60% survival. The drug inhibited virus replication with the virus mutating over time. Even though this data was published after the EBOV epidemic in West Africa, clinical trials of favipiravir were still conducted during the epidemic, since this drug was the only one available with a fairly well-known safety profile in humans, oral bioavailability, and demonstrated efficacy in EBOV-infected mice. The drug was also used in patients evacuated to Europe and the USA. Unfortunately, despite the clinical trial data and data obtained from repatriated cases, a beneficial effect of favipiravir in EVD patients could not be demonstrated.

Remdesivir, also known as GS-5734, has been shown to prevent lethal EVD in NHPs when a relatively high intravenous dose of 10 mg/kg was initiated three days after infection and continued once daily for 12 days. The drug was used in a relapsed EBOV patient who had been evacuated to Europe and treated with other experimental drugs during the epidemic. Remdesivir is currently being used with good success in the ongoing outbreak in the DRC. A first report from the outbreak demonstrates that patients receiving an intravenous dose (200 mg) on day 1 followed by daily treatment with 100 mg until days 9–13, depending on virus load, had a ~50% survival rate. Interestingly, ~85% of people with a high viral load at the start of treatment survived, compared to 29% survival in patients with a low viral load. Although the efficacy of remdesivir is lower than those of mAb114 and REGN-EB3, remdesivir has the potential for combination therapy. No preclinical data is yet available for combined approaches.

Prevention

Treatment strategies are the best option during an outbreak; however, when an entire population of an endemic area needs to be protected from a disease, vaccination is the best preparedness strategy. For EBOV, vaccine development started shortly after the virus was discovered. Early vaccine approaches included inactivated virus and vaccinia virus-based vaccines. While these vaccines protected rodents from disease, NHPs were not protected. With additional funding becoming available in the early 2000s for countermeasure development against potential bioterrorism pathogens, efforts to develop an EBOV vaccine increased. Several vaccine platforms were developed most of which used EBOV GP_{1,2} as the antigen, including DNA-, protein-, and virus-like particle (VLP)-based vaccines, as well as virus-vectored vaccines based on alphavirus replicons, adenoviral vectors, modified vaccinia Ankara (MVA), human parainfluenza virus 3, rabies virus, and vesicular stomatitis virus (VSV). Although each of these vaccine approaches showed preclinical efficacy in NHP studies, there was limited interest from pharmaceutical companies to bring any of them to licensure. The situation changed in 2014, however, during the unprecedented West African epidemic, when most vaccination strategies with preclinical efficacy and an industrial partner for production were accelerated into human clinical trials worldwide. While these clinical trials involved several different vaccination approaches with demonstrated immunogenicity and safety in humans, this article will focus on the two most promising candidates that are currently being used in the ongoing

outbreak in the DRC. Notably, while China and Russia both licensed EBOV vaccines in 2018 (without human efficacy data), these vaccines are currently not being used in the DRC.

Adenovirus 26 (Ad26) & Modified Vaccinia Ankara (MVA)

The deletion of genes essential for replication in the adenovirus genome produces a replication-deficient particle that can be used as a vector for an antigen of choice, such as EBOV GP. Indeed, human adenovirus 5 expressing EBOV GP_{1,2} was first used to generate an EBOV vaccine, but it was shown to have limited efficacy due to pre-existing adenovirus immunity in the human population. In order to circumvent this problem, several other adenoviruses, including human adenovirus 26 and 35, as well as chimpanzee adenovirus 3, were developed expressing EBOV GP_{1,2}. Vaccination with an adenovirus 26-based vaccine (known as Ad26-EBOV) resulted in strong humoral immune responses and was able to protect NHPs from a lethal EBOV challenge. However, at least two doses were needed for protection and there were concerns with the longevity of the protective immune response. In order to address these concerns, a prime/boost strategy was implemented using Ad26-EBOV as a prime vaccination followed by a boost with the replication-incompetent MVA encoding GP_{1,2} (known as MVA-EBOV). This vaccination approach offered 100% protection in NHPs and has since been evaluated in several phase 1 human clinical trials, starting during the West African epidemic. The trials demonstrated a good safety profile and immune responses specific to EBOV GP. The Ad26-EBOV/MVA-EBOV vaccine approach is currently being used in the DRC in areas with no active EBOV cases to help increase the number of protected people with the hope to end the large ongoing outbreak in that country.

Vesicular Stomatitis Virus

In contrast to Ad26 and MVA, the VSV-based EBOV vaccine is replication competent. The VSV glycoprotein was removed in this vector and replaced with EBOV GP_{1,2}. Preclinical efficacy in NHPs was already demonstrated in 2005, yet no industry partner was found to produce human-grade vaccine until 2013. Further preclinical studies with NHPs demonstrated that a single dose of the VSV-EBOV vaccine is fast acting, protecting the animals within one week of vaccination; however, the longevity of the protective immune response remains unclear. During the West African epidemic, several phase 1–3 human clinical trials were conducted world wide, including a phase 3 trial in Guinea that demonstrated that a single dose of the vaccine was efficacious and prevented new infections. As this is a replication-competent vaccine, mild to moderate adverse effects after vaccination with a single dose of VSV-EBOV were reported. This vaccine has been used since the beginning of the ongoing outbreak in the DRC with remarkable success.

Remarkably, the VSV-EBOV vaccine was licensed (under its commercial name ERVEBO) in November 2019 by the European Medicines Agency and a month later by the US Food and Drug Administration. With the long-awaited clinical licensure of VSV-EBOV, as well as the licensing of separate vaccines in Russia and China and the anticipated licensure of Ad26-EBOV/MVA-EBOV, there is increasing hope that future EBOV outbreaks will be rapidly contained and no longer pose a threat to global public health.

Glossary

Acute flaccid paralysis Any sudden weakness or loss of muscle tone.
Onychomadesis Shedding of the nails.

Recombination Process by which genetic material is broken and joined to other genetic material, genetic rearrangement.

Classification (Compact)

Enteroviruses form one of the largest group of viruses, which infects both humans and other species. Currently, there are more than 150 enterovirus types in 15 species. Most types infect humans but enteroviruses have also been identified in many mammals including bovines, pigs, monkeys, dromedary camels and rodents. Within species different types share greater than 70% amino acid (aa) identity in the polyprotein, greater than 60% identity in the capsid protein coding region (P1), and greater than 70% aa identity in the non-structural proteins 2C + 3CD. They also have a limited range of host cell receptors, a limited natural host range, a genome base composition within a 2.5% variation range as well as significant compatibility in proteolytic processing, replication, encapsidation and genetic recombination. Current EV typing system is based on genetic relationships of VP1 capsid protein.

Human enteroviruses are currently classified based on their genome organization, sequence similarity and biological properties into four species: Enterovirus A (EV-A), EV-B, EV-C and EV-D (**Fig. 1**), and include representative members such as polioviruses, coxsackie A and B viruses and echoviruses. The most recently identified types have been named according to numbering and species convention, such as enterovirus B-100. Each human enterovirus species consists of types; 25 EV-A types, 63 EV-B types, 20 EV-C types including 3 poliovirus types and 5 EV-D types (**Fig. 1**). Types can be distinguished by nucleotide sequence identity in the VP1 protein coding region. Identity of at least 75% (85% aa identity) between a prototype strain and an isolated strain suggests serotypical identity given that the next highest identity with an other prototype strain is less than 70%. Recent evolutionary studies indicate, however, that for e.g., CVA13, CVA20, E1, E13 and E30 nucleotide sequence identity within type may even be 73%, and thus amino acid identity should also be used as the basis of type determination. Within types enterovirus can further be classified into subtypes or genotypes with demarcation cut-offs varying between 9%–20% in the VP1 protein coding region. Genomic regions outside the capsid do not correlate with serotype identity due to frequent recombination in the non-structural parts of the genome.

The sequence relatedness in the P1 region coding for the capsid proteins correlates reliably with the traditional definition of a serotype. Antigenic groupings known as serotypes share similarities in immunologic response of the human host, protection from the disease, receptor usage and to some extent symptoms of clinical disease. Within a serotype isolates can be distinguished based on antigenicity measured with antisera raised in animals. Serotype still remains an important physical and immunologic property distinguishing different enteroviruses.

Most of the prototype strains of enteroviruses were originally isolated in the 1940–1950s. Development of molecular methods has facilitated detection of new enterovirus types during the past twenty years. In addition, molecular epidemiological studies have indicated the need for re-classification of some types, e.g., human rhinovirus 87 as EV-D68 and closely related rhinoviruses as three different species under the genus *Enterovirus*.

Fig. 1 Phylogenetic tree depicting genetic relationships of enterovirus types in *Enterovirus* species A to D. The evolutionary history was inferred by using the Maximum Likelihood method and Tamura-Nei model. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 116 nucleotide sequences coding for the complete VP1 capsid protein region. Evolutionary analyzes were conducted using MEGA vs. 10.0.5.

Enteroviruses evolve through mutations and recombination events. Substitution rates within types are in the range of 0.41×10^{-2} to 3.07×10^{-2} substitutions per site per year. According to recent evolutionary analyzes times of the most recent common ancestors of individual enterovirus types vary between 55 and 200 years ago. Both inter- and intratype recombination events are common. Recombination occurs more frequently in the non-structural protein coding region and is restricted to viruses belonging to the same species. Interspecies recombination has been detected in the 5' NCR and VP4 junction.

Virion Structure

Enteroviruses were the first animal viruses for which structures with atomic detail were determined. Since 1985, when the X-ray structures of poliovirus and rhinovirus B-14 were determined, numerous high-resolution enterovirus particle structures with

Fig. 2 Enterovirus structure. The capsid consists of 60 protomers, each consisting of four polypeptides that comprise the structural proteins VP1, VP2, VP3, and VP4 within capsid. VP4 faces the interior and is not visible on capsid surface. Cryo-EM model of coxsackievirus A7 (left). Reproduced from Seitsonen, J.J., Shakeel, S., Susi, P., *et al.*, 2012. Structural analysis of coxsackievirus A7 reveals conformational changes associated with uncoating. *Journal of Virology* 86, 7207–7215.

similar particle architecture have been resolved. Enterovirus particles are spherical with a diameter of about 28 nm and a density close to 1.34 g/ml, which is less than in most picornaviruses. Virus particles lack lipid membrane, which makes them insensitive to organic solvents and sturdy enough to ensure survival in harsh conditions in the gut where they replicate. Most enteroviruses are acid stable and retain infectivity at pH values lower than 3.0. However, virus particles are also flexible and able to undergo structural rearrangement during the entry and uncoating processes to release viral RNA.

Core particle features include small and smooth icosahedral structure and modularity of viral subunits with conserved Swiss roll domains. Enterovirus particles are constructed of 60 repeated protomer units, which are composed of four structural proteins, VP1 to VP4, encoded by proteolytic processing of long viral polyprotein (**Fig. 2**). The protomers form an icosahedral shell with a pseudo- $T = 3$ arrangement that encapsidates the viral RNA genome. External VP1 proteins are located around the five-fold axes, while VP2 and VP3 alternate around the 2- and 3-fold axes. These proteins have no sequence homology, but they share similar protein topology; each protein adopts eight-stranded, antiparallel β -barrel fold (Swiss roll) with C-termini located on the surface of the virion and N-termini facing the interior, which allows the formation of a dense and rigid protein shell. The main structural differences between VP1, VP2 and VP3 can be found in the loops that connect the β -strands and in the extended N- and C-termini. The amino acids within these domains define the morphology and antigenicity of the enterovirus types. VP4 is a short myristoylated capsid protein located in the interior of the virion. Viral RNA is tightly packaged within the capsid and in direct contact particularly with N-terminal amino acid residues of VP4. The N-termini of capsid proteins together with the myristate of VP4 have a major role in virus assembly and stability of the particle.

Most enteroviruses have a deep surface depression – also known as “canyon” – encircling the five-fold axes of symmetry that often serves as the cellular receptor binding site. The surface area of receptor binding in the canyon has been proposed to allow neutralization by neutralizing antibodies, which block viral infectivity, but also immune evasion of enteroviruses via mutations. Since VP1 is located around the five-fold axes and accounts most of the accessible surface, it is the most important target for neutralizing antibodies. VP1 is also the most variable and immunogenic particle protein. However, not all enteroviral receptors bind to the canyon structure suggesting that other mechanisms of neutralization (and immune evasion) exist. Indeed, several mechanisms for antibody neutralization besides interference with receptor binding has been proposed; virus stability, uncoating or virus aggregation may be affected by neutralizing antibodies.

The floor of the canyon within the VP1 β -barrel of all enteroviruses harbors a small, hydrophobic tunnel or pocket, which is in some enteroviral structures filled with a lipid moiety (for example, sphingosine, lauric acid or myristic acid) and likely to be involved in regulating particle stability. This pocket has been extensively studied for the development of novel antiviral substances. Several clinical trials have been performed with antiviral capsid binders, known as the WIN compounds (produced by Sterling-Winthrop and Janssen Pharmaceuticals). These molecules occupy the hydrophobic pocket and displace the pocket factor, thereby increasing particle stability and preventing receptor binding and/or genome release. However, antiviral effects *per* enterovirus type and clinical benefits have not been sufficient for clinical approval and use.

As of January 2019, there are 147 structure depositions for enterovirus structures in the VIPERdb (see “Relevant Websites section”) including native structures and structures of mutant viruses, viruses complexed with receptors, antiviral compounds, peptides and antibody fragments determined by X-ray crystallography or cryo-electron microscopy. Progress in high-resolution cryo-electron microscopy techniques is likely to increase the number of high-resolution structures in the near future and to enhance our understanding of the structural diversity within the family *Picornaviridae*. Expedited structure determination is also likely to facilitate research on antiviral capsid binders.

Fig. 3 Enterovirus genome organization and polyprotein cleavage patterns.

Genome

Enterovirus genome is a single positive-stranded RNA molecule with a length of approximately 7500 nucleotides (**Fig. 3**). Enteroviral RNA can function as a messenger RNA (mRNA) and it is infectious. At the 5' end of the genome there is a covalently linked VPg protein (virion protein, genome linked). VPg is not required for infectivity, but it is suggested to act as a primer for RNA synthesis.

The structure of the genome (**Fig. 3**) is common among many picornaviruses. The 5'-non-coding region (NCR) with an approximate length of 700 nt controls genome replication and translation. It harbors the internal ribosome entry site (IRES) that directs translation of the mRNA by internal ribosome binding. In the 3' end of the genome there is a short, less than 100 nt, 3'NCR. It has also a secondary structure, a pseudoknot, that controls viral RNA synthesis. The genome ends with a poly-A tail in both virion and mRNA. The poly-A tail has an effect on infectivity; the genome is non-infectious if the poly-A tail is removed.

Between the NCRs there is a single long open reading frame (ORF). The ORF is processed to form individual viral proteins. The gene expression is also similar in all picornaviruses including EVs. The polyprotein cleavage occurs during translation by virus-encoded proteinases. The polyprotein is divided in three regions: P1-3 (**Fig. 3**). P1 encodes viral capsid proteins, P2 and P3 encode non-structural or functional proteins. 2A^{pro}, 3C^{pro}, 3CD^{pro} are involved in protein processing and 2B, 2C, 3AB, 3B^{VPg}, 3CD^{pro}, 3D^{pol} in genome replication.

Life Cycle

To complete a successful infectious cycle, an enterovirus must proceed via several steps including attachment, internalization/entry, endocytosis, replication, particle assembly and exit (**Fig. 4**). Recognition of cell surface receptor(s) by virus particle determines the host range and tropism of cell and tissue infection and is the first step in the virus replicative cycle. Currently, there are more than ten different receptors known to mediate enterovirus infection, which may explain the numerous diseases that are caused by enteroviruses. These include e.g., CAR (coxsackievirus-adenovirus receptor), CD54 (intercellular adhesion molecule 1; ICAM-1), CD55 (decay-accelerating factor, DAF), CD155 (poliovirus receptor, PVR), integrin (e.g., $\alpha 2\beta 1$, $\alpha V\beta 1$, $\alpha V\beta 3$, $\alpha V\beta 6$), heparan sulfate and sialic acids. Cellular receptors are classified as true receptors (a cell surface protein or sugar moiety) that mediate internalization and/or genome release and co-receptor(s)/attachment factors (e.g., heparan sulfate) that act in the attachment of a virus to cell surface. For some enteroviruses, a single cellular receptor functions in both binding and entry (e.g., PVR) while other enteroviruses use several receptors in a coordinated fashion where binding to the "first" receptor leads to signaling cascade that allows the virus to bind to the true entry receptor (e.g., DAF-CAR).

Virus binding to the cell surface receptor may initiate a cascade of events leading to extensive irreversible structural changes (externalization of the N-termini of VP1 and the release of VP4) or have no effect on virus structure. Irrespective of this, most enteroviruses are internalized via receptor-mediated endocytosis mechanism (receptor itself is not known to be endocytosed) and transported to the cytosolic replication site in endosomal vesicles for viral RNA release instead of direct release of viral RNA into cell cytosol upon contact with the receptor. Nevertheless, the receptor usage is highly dependent on cell type, virus strain or even virus passage number (due to adaptation), and therefore, the actual role of any of these molecules in clinical infection needs further studies.

While the endocytic process has been analyzed in detail for only a few enteroviruses, it is evident that they can use several endocytic mechanisms. Previously, endocytosis was divided into clear-cut mechanisms, such as clathrin- or caveolin-mediated endocytosis, but more recently it has become evident that there are more exceptions than rules to enterovirus entry mechanisms. That is, the virus entry is defined by pathway-specific entry components. For example, poliovirus (PV) is internalized using actin

Fig. 4 Enterovirus life cycle. Following the binding to cell surface receptor(s), virus is endocytosed into the cell cytoplasm, where its positive-strand (+) RNA genome is released from viral capsid and used in translation and genome replication. Viral protein VPg (3B), which is used as primer in replication, is covalently linked to viral genome. Genome translation yields a single polyprotein that is proteolytically cleaved into replication proteins (2A–2C and 3A–3D) and capsid proteins (VP0, VP1 and VP3), which are used to make new viral capsids. Genome replication is mediated by viral RNA-dependent RNA polymerase (3D), which synthesizes negative-strand (–) RNAs that serve as templates for synthesis of new (+) RNA molecules. New (+) RNA molecules can either enter a new round of replication or be packaged into progeny virions. Capsid proteins self-organize into protomers and pentamers and assemble into provirions that are converted into infectious, mature virions by genome-induced cleavage of VP0 into VP4 and VP2. Mature virions exit the cell via non-lytic release of extracellular vesicles or via cell lysis.

and tyrosine kinases but not clathrin, caveolin or microtubules with rapid release of viral RNA in the periphery of HeLa cells. In contrast, in endothelial cells PV entry occurs slowly and is dependent on caveolin-1 and dynamin. There are also no rules for receptor-specificity and endocytosis. Echovirus 7 (E7) uses DAF as the primary receptor, but it is endocytosed via a clathrin-mediated pathway, while coxsackievirus B3 (CVB3) entry via DAF is caveolin-1-dependent. In addition, the entry process of CVB3 requires occludin but not dynamin. Echovirus 1 (E1) uses specifically integrin $\alpha 2\beta 1$ receptor in a process involving components of macropinocytosis, such as PKC, Pak1 and Rac1, and ESCRT proteins. Recent studies within *Enterovirus B* species have revealed remarkable similarities between virus types, which use a variety of cellular entry receptors, and it is apparent that many factors contributing to endocytosis are associated with macropinocytic uptake. These examples imply that enterovirus entry pathways are subject to virus type (and strain), cellular receptor and cell line used in the study.

Viral RNA release or uncoating follow the endocytosis to the site of replication. This may result in conformational changes in the virus particles, which are detected by sedimentation of virus particles with different molecular weights (160S for native particles versus 135S) in a differential ultracentrifugation run. According to some studies, the resulting 135S particles have exposed N-terminus of VP1 and lack VP4 but contain viral RNA. It has been hypothesized that hydrophobicity of VP1 N-termini increase the affinity of 135S forms to vesicular membranes, and as a result a pore through which viral RNA is released to cytosol is formed. The directionality of enteroviral RNA release during uncoating is unknown but it has been shown for a related rhinovirus (RV-A2) that the 3' end of the genome exits the virion before the 5' end. The site of RNA release from the virions is under debate and subject of virus type; the release may occur both at the two-fold, near the quasi-three-fold and five-fold axes depending on the cues used to trigger the uncoating process (such as heat, acid or soluble receptor molecules).

The mechanism of RNA replication is well conserved among all enteroviruses; it is mediated by an internal ribosome entry site (IRES), and requires several IRES trans-acting factors and a non-canonical replication machinery assembled on virus-induced ER-derived membrane structures enriched with phosphatidylinositol-4-phosphate and cholesterol lipids. These lipids regulate the activity of the replication machinery and its core enzyme, viral-encoded RNA-dependent RNA polymerase (3Dpol), and thus viral RNA synthesis. After delivery to the cytosol, viral RNA is directly translated by ribosomes into a single large polyprotein, which is proteolytically processed by viral proteinases, 2A^{pro}, 3C^{pro} and 3CD^{pro}, into functional proteins that mediate both genome replication and virus assembly. Genome replication by 3D^{pol} is initiated with the synthesis of negative-stranded RNAs of the viral genomic RNAs to generate double-stranded RNA

Table 1 Clinical disease entities associated to enterovirus types

<i>Disease</i>	<i>EV types most often detected</i>	<i>Comments</i>
<i>AFP/AFM</i>	PV, EV-D68, EV-A71	PV cases almost ceased. Other types associated include CVA7, CVA9, CVB1-B6, echoviruses, EV-D70
<i>AHC</i>	EV-D70, CVA24 variant	
<i>Encephalitis</i>	EV-A71	All EV types
<i>HFMD/herpangina</i>	CVA6, CVA10, CVA16, EV-A71	CVA1-A5, CVA8, CVA22 CVB types and echoviruses associated more rarely
<i>Meningitis</i>	Echoviruses, CVA and CVB viruses, EV-A71	All EV types
<i>Myocarditis</i>	CVB1–6	
<i>Neonatal sepsis</i>	CVB2-B5, E11	E5, E6, E16, E19 have also been associated to severe sepsis
<i>Pleurodynia</i>	CVB1–6	CVA types and echoviruses rarely
<i>Respiratory disease</i>	EV-D68, CVA21, CVA24	All EV types

replication intermediates. After strand separation, the negative strands serve as templates for the synthesis of new positive-stranded viral RNAs, which subsequently serve as templates for new rounds of replication or IRES-guided translation. Capsid proteins assemble into protomers and pentamers, which together with viral RNAs form mature virions. Thus, the particle assembly is directly coupled with the viral RNA replication. Besides cleaving the viral polyprotein, viral proteinases 2A^{Pro} and 3C^{Pro} cleave several host proteins to optimize virus translation, replication and virus spread and to suppress antiviral cellular responses. This leads to morphological alterations and ultimately virus particle release by disruption of cellular membranes. However, enteroviruses can also egress non-lytically in phosphatidylserine enriched, non-canonical autophagosome-like vesicles. This exit strategy may provide a simultaneous (masked) route of transmission of multiple genomes to uninfected cells, which enables the virus to maintain the viral genetic integrity and evade the immune system.

Epidemiology

Enterovirus infections are very common. Age, socioeconomic status and sex have an effect on the frequency and outcome of the infection. Enteroviruses are seen in people of all ages, but children are most prone due to lack of protecting antibodies from previous infections. Also the severity of infection, variety of clinical symptoms and prognosis varies between different age groups with children more likely to present with significant clinical symptoms. Encephalitis and aseptic meningitis are most frequently seen in children 5–14 years of age. Encountering the first enterovirus infection at an older age increases the severity of symptoms. Enterovirus infections are more prevalent among people with low socioeconomic status as well as in those living in urban areas. Males, in general, are more prone to enteroviral disease and severe infection than females.

Enterovirus infections typically peak during summer and early autumn in temperate climates. In tropical environments enterovirus infections occur all year round or they are associated with rainy seasons. Enteroviruses are isolated from both lower and upper gastrointestinal tract and are readily excreted to feces. They survive for extended periods, i.e., months, in the environment, e.g., sewage, in favorable conditions. Neutral pH, moisture, low temperature and presence of organic matter protect enteroviruses from inactivation.

The main form of transmission of enteroviruses is via fecal-oral route; from respiratory/upper gastrointestinal tract to the gut and from there to the brain. Also, respiratory transmission occurs for certain types, e.g., EV-D68, and to a lesser extent, mother-to-infant transmission. Hand contact of upper respiratory mucosa (mouth, nose, conjunctiva) may facilitate transmission. Transmission occurs readily within households, neighborhoods and communities. In addition, nosocomial transmission has also been reported, especially among newborns. Humans are thought to be the main reservoir of enteroviruses. Simian enteroviruses are genetically closely related and human enteroviruses have been detected in free-living non-human primates. In addition, swine vesicular disease virus is a porcine variant of CVB5.

Based on seroprevalence studies neutralizing antibodies are readily found in different populations indicating high incidences of past infections. Some enterovirus types are considered to remain endemic in certain areas, e.g., EV-B type E11 in Europe, whereas other viruses cause outbreaks with 5–10 year intervals, e.g., E30. Nucleic acid sequencing and molecular epidemiology have been widely used as a tool for the detection of genetic relationships of enteroviruses and identification of epidemiological patterns. Molecular epidemiology has provided information on geographic and temporal origin of the strains to strengthen epidemiologic links, to observe similarities among isolates in an outbreak and differences among isolates in different geographic regions.

Clinical Features

Most enterovirus infections are clinically unnoticeable. When symptoms occur, the prevailing clinical presentations are common cold, non-specific febrile illness and/or rash, which are indistinguishable from diseases caused by other viruses. However,

enteroviruses can cause a variety of more specific clinical outcomes, e.g., hand-foot-and-mouth disease (HFMD), meningitis, encephalitis, acute flaccid paralysis/myelitis, conjunctivitis, sepsis-like disease in newborns and myocarditis (Table 1). Different enterovirus types can cause similar diseases during the same geographically restricted outbreak and, vice versa, one type can cause a variety of clinical symptoms.

Hand-foot-and-mouth disease is the most significant form of clinical enterovirus infection globally. The WHO defines HFMD as a febrile illness with papulovesicular rash on palms and soles with or without vesicles/ulcers in the mouth. In herpangina, the patient has febrile illness with multiple oral ulcers on the posterior parts of the oral cavity. Causative agents are species A enteroviruses and usually multiple different types co-circulate in HFMD outbreaks. The incidence of CVA16 is high world-wide. CVA6 emerged in 2000s and alternates with CVA16 as the most common enterovirus in outbreaks. EV-A71 has caused extensive HFMD outbreaks especially in the Asia-Pacific region during last decades.

In most cases, HFMD and herpangina are self-limiting diseases, recovery occurs within 1–2 weeks after onset, and skin blisters heal without scarring. Onychomadesis is a recently reported specific consequence of CVA6 infection. Severe HFMD complications are rare, but occasionally central nervous system (CNS) is involved, particularly in children under 5 years of age, and when the causative agent is EV-A71. During recent EV-A71 outbreaks in Asia, 10%–30% of hospitalized HFMD patients developed CNS complications such as meningitis, brainstem encephalitis, encephalomyelitis and/or acute flaccid paralysis. The most severe EV-A71 cases have acute refractory myocardial dysfunction and fulminant cardiorespiratory failure with relatively high mortality rate. The survivors are in high risk for long-term sequelae, which range from limb weakness to ventilator dependence and presence of multiple physical and psychobehavioral disabilities. The severity of the disease depends on multiple factors, including age of the patient, pre-existing immunity, co-infections and the type and (sub-) genotype of the outbreak virus strain. The susceptibility to a severe EV-A71 infection may be associated with certain HLA types of the host as well.

Enteroviruses are the most important causes of meningitis, an inflammation of the tissue covering brain and spinal cord. Individuals of all ages can contract meningitis, but most prone are children younger than 5 years of age and people having impaired immune system. Typical symptoms are headache, fever, muscle and stomach aches, stiffness in the neck, photophobia and phonophobia. The prognosis is usually good and the infection is cleared in one to two weeks. The prominent causative enterovirus types are echoviruses and coxsackie B viruses. Large outbreaks may occur in the summer-fall season in temperate climates. Encephalitis is a more severe presentation of CNS infection. The direct inflammation of brain can be caused by many enterovirus types, but it is mostly associated with EV-A71.

All enteroviruses can cause respiratory symptoms. The disease spectrum includes acute upper respiratory infection, pneumonia, bronchiolitis, wheezing, respiratory distress and asthma exacerbation. Enteroviruses have also been detected in the middle ear fluid in young children at the time of acute otitis media. EV-D68 has long been associated with respiratory diseases and, at least some of the strains, share biological properties, like acid-sensitivity, with human rhinoviruses. Clinical isolates of EV-D68 were rare up to 2005. Since then, EV-D68 has caused wide outbreaks with considerable proportion of severe respiratory infections. Especially young children may require hospitalization and intensive care due to bronchiolitis or pneumonia. In rare cases, and mostly in young children, EV-D68 infection has been lethal.

Acute flaccid paralysis (AFP), is a case definition used in poliovirus surveillance, meaning any sudden weakness or loss of muscle tone. Acute flaccid myelitis (AFM), is a more specific definition for a paralytic case with lesions in the brainstem and spinal cord gray matter, which are detectable by magnetic resonance imaging. CSF findings in enterovirus AFM are non-specific, lymphocytic pleocytosis is mild to moderate, glucose is normal and protein levels are normal or elevated. Virus is not usually detected in CSF. In the past, the most important AFP/AFM causing enteroviruses were polioviruses. In the 2010s, when poliovirus eradication is almost complete, most of the AFP/AFM cases are caused by other, non-polio enteroviruses. During EV-D68 outbreak in the US and Canada in 2014, the incidence of AFM followed that of EV-D68 respiratory disease. EV-D68 was detected in CSF in only few cases, but more often in the respiratory specimens on the onset of AFM. The full recovery occurred in only a small percentage of the EV-D68 AFM patients, and the majority had residual weakness still one year after the onset. In EV-A71 HFMD cases, the onset of paralysis may occur in 2–6 days after the first symptoms.

Newborns are susceptible to severe enterovirus diseases, although the majority of enterovirus infections are asymptomatic or mild in neonates as well. The most severe presentation of neonatal enterovirus disease is septic shock with multiorgan failure. The disease can include specific manifestations like pneumonia, hepatitis, pancreatitis, myocarditis, meningitis or encephalitis. Mortality is highest in neonates with both hepatitis and myocarditis. Neonates with symptomatic enterovirus infection usually have mother or other contact with recent symptomatic illness. Perinatal transmission is also possible. Severe disease has been associated especially with CVB2 – CVB5 and E11.

Acute hemorrhagic conjunctivitis (AHC), first detected in 1969, is a highly contagious infection of eyes. EV-D70 and a variant of CVA24 are the leading causative agents of AHC and have caused pandemics as well as smaller outbreaks world-wide. In addition to general symptoms, like fever, sore throat and headache, the infection results in eye irritation, photophobia, discharge and subconjunctival hemorrhage, which ranges from discrete petechiae to large patches of hemorrhage covering the bulbar conjunctiva. Recovery is usually complete within less than 10 days without ocular sequelae. During EV-D70 pandemics, neurological symptoms were reported in about 1 out of 10 000 AHC patients.

Viral myocarditis, pericarditis and myopericarditis are rare consequences of EV infections, usually caused by coxsackie B viruses. Bornholm disease or epidemic pleurodynia, also known as epidemic myalgia, is caused by coxsackie B viruses. The typical symptom of Bornholm disease is acute, severe pain in the chest, often only on one side. Other symptoms include headache, fever, sore throat and general malaise.

There is also evidence that some enteroviruses may trigger onset of chronic diseases. Some coxsackie B viruses and echoviruses are associated to the onset of type 1 diabetes, but the exact mechanisms are not yet fully understood.

Pathogenesis

Polioviruses were historically the model of enterovirus pathogenesis research. With the success of the on-going poliovirus eradication campaign (see “Relevant Websites Section”) pathogenesis research of other enteroviruses has gained increasing interest. The most current research on enterovirus pathogenesis is focused on coxsackie B viruses, particularly CVB3, and enterovirus A71 (EV-A71) in Asia. The prevalence, modes of transmission, genetic variability (quasispecies), spectrum of tropism, specific features in cellular life cycle and ability to cause both lytic and persistent infections in the human host make it challenging to not only recognize but also link prior enteroviral infections and subsequent chronic syndromes.

Primary infection occurs via respiratory or gastrointestinal tract mucosa. Viremia infection occurs within a day after contact with the virus enabling virus dissemination to multicellular organs, and lasts for 7–14 days until it is cleared by virus-activated adaptive immune response. Enteroviruses also replicate in actively proliferating cells, which are evident during organ development in the young. In addition, infectivity in the young may be related to tropism, i.e., expression of virus-specific cellular receptor in target cells, and more specifically to age-related expression of virus receptors, such as CAR in case of coxsackie B viruses. Enteroviruses have been shown to infect muscle, heart, pancreas and CNS causing respective diseases (see Section Clinical Features), some of which can be fatal or result in long-lasting organ dysfunction. CVB3 has tropism to heart and pancreatic tissues and is thus causative agent of virus-induced myocarditis and pancreatitis while EV-A71 is considered to be a serious emerging CNS pathogen.

Since EVs are transmitted via fecal–oral route of infection, a detailed understanding of how the virus travels from the gut to the brain is essential in order to understand the pathogenesis. It is possible that during viremia virus passively passes blood-brain-barrier (BBB) independent of receptor interactions. However, it is more likely that virus dissemination between organs is at least partially defined by tissue tropism. The current model favors the idea that virus infects CNS using “Trojan horse” tactic by infecting myeloid stem cells, which mask the virus from the immune system and enable long-distance dissemination from the gut to CNS.

At cellular level the most prominent feature of EV infection is cytolysis, i.e., ability to cause direct cell lysis following virus replication. In cells, EVs shut-down host protein synthesis and inhibit host cell protein secretion by virus-specific 2A and 3C proteases and 2B and 3A proteins, respectively. In addition, enteroviruses benefit from a cellular degradation process known as autophagy, which is known to play an important role particularly in preventing cellular damage in neurons. EVs use autophagosomal membranes as scaffolds for viral replication, which eventually leads to cytopathic cell lysis. It has also been suggested that EV proteins possess pro-apoptotic properties promoting cell death.

Enteroviruses are known to persist (i.e., to cause infection in which virus is not cleared but remains silent in specific cells) up to 90 days with occasional activation of virus with disease symptoms. The genetic mechanism by which enteroviruses persist is apparently related to the RNA genome; enteroviral genomes with the first 49 nucleotides deleted have been detected in samples from human heart and in murine model of chronic myocarditis. This results in virus variants that replicate slowly and express very low levels of genomic RNA. As a consequence, enteroviruses that do not induce cytolysis are generated in barely detectable amounts. During the persistent infection viral 2A protease is expressed. Viral 2A protein has been shown to cleave dystrophin, which is a vital heart protein that supports muscle fiber strength. Cleavage of dystrophin is thought to contribute to dilated cardiomyopathy. It is not known whether autophagy contributes to viral persistence. CVB3 infection in CNS tissue may be linked to its ability to establish persistent infection only in such target stem cells, which support sporadic reactivation whenever they become activated to generate downstream progenitor cells. Together with cellular effects, this data may explain why enterovirus is the most important causative agent of aseptic meningitis.

Despite of vast number of cellular studies and epidemiological studies with phylogenetic analyzes, relatively little is known about the determinants of enteroviral virulence. In general, there are not many publications where a single amino acid mutation is linked to changes in disease symptoms. This is greatly related to quasispecies nature of enteroviruses, which makes it difficult to identify a uniform virus (population) with a disease-related point mutation. Nevertheless, differences may lie in either NCRs, capsid or functional regions. For example, CVB4-VP1 gene has been linked to CVB4-induced pancreatitis; VP1 mutation in a virulent strain increases both virus amounts and immunogenicity enhancing disease symptoms. Studies with chimeric viruses (generated by the exchange of fragments between the attenuated and the virulent strains) have suggested that the 5′-NCR plays a major role in poliomyelitis and myocarditis, latter of which is directly related to enterovirus persistence with 5′-terminal deletions. However, it is evident that many genomic regions contribute not only to symptom development in myocarditis but also to other disease phenotypes.

Diagnosis

Enterovirus diagnosis is based on the detection of enterovirus or its genome from appropriate clinical specimens. Clinical diagnosis is rarely adequate enough because enterovirus symptoms are indistinguishable from other viral or bacterial diseases. Only in well-described community outbreaks, where circulation of a particular enterovirus type is confirmed, the diagnosis may rely solely on clinical and epidemiological findings.

Stool specimens and rectal swabs are the most sensitive for enterovirus detection. Viruses are excreted in stools in large concentrations, and this may last few weeks or even months after the recovery. In AFP/AFM, two stool specimens should be collected and analyzed for poliovirus. Respiratory specimens are a good choice especially in the beginning of the disease and they are obligatory for detection of e.g., EV-D68. Challenging in the non-sterile respiratory and intestinal tract specimens is that the etiological connection to the disease cannot be assured, as a significant proportion of healthy individuals are positive for enteroviruses as well. Specimens collected according to the symptoms are recommended for confirmation of the diagnosis. CSF is analyzed when CNS is involved and, with the exception of EV-D68, EV-A71 and polioviruses, enteroviruses can be detected in most meningitis cases, but rarely in encephalitis. From newborns with a systemic sepsis-like disease, blood is used as a supplementary specimen for enterovirus detection. In AHC, enterovirus is most frequently detected in conjunctival and oropharyngeal specimens. Vesicle swabs contain a high viral load in cases of HFMD and herpangina. Biopsy samples, including nails in onychomadesis, can be analyzed as well.

The specimens should be collected as soon as possible after the symptoms have appeared, but at least within four days of the disease onset is recommended. The virus can be detected e.g., in feces for weeks, but etiological connectivity to the disease decreases in time.

The detection of enteroviruses is performed almost solely by molecular methods, and particularly by real-time PCRs. The PCR exceeds the traditional virus isolation both in speed and sensitivity. For enterovirus genome detection, the most sensitive assays rely on highly conserved sequence stretches in the 5' NCR of the genome. There are numerous published in-house protocols guiding the set-up of sensitive and specific assays. Commercial assays are available for either detection of enterovirus only or detection of enterovirus together with other major respiratory, neurotropic or gastrointestinal viruses by multiplexed PCR assays. The 5' NCR assays are highly sensitive, but allow the detection only in the pan-EV level, not in the type level. It is also noteworthy that some of the 5' NCR protocols do not separate enteroviruses from human rhinoviruses, which is a challenge when respiratory samples are analyzed.

Enterovirus type-specific diagnosis is based on the sequences of the capsid coding parts of the genome. The VP1 coding region is the best one for EV typing as it has the most prominent antigenic sites, which are the basis for the classification of enteroviruses. Type-specific real-time PCRs have been designed for example HFMD causing strains CVA6, CVA10 and EV-A71 and these both confirm the presence of enterovirus and type the virus in one PCR reaction. Specific PCR assays are especially useful in large outbreaks, when rapid screening of large amounts of clinical specimens is needed.

Sequencing of the VP1 coding region or its part is a common practice in many clinical and national laboratories. This can be done directly from the clinical specimens, but the assay is usually less sensitive than the PCRs targeting the 5' NCR and it is not recommended for the first choice in diagnostics. The appr. 350 nucleotide long sequence from the amino-terminal region of the VP1 gene is sufficient for reliable typing and molecular epidemiological studies. The complete VP1 sequence is needed for the classification of a new enterovirus type. In addition to VP1, occasionally coding regions for proteins VP4 and VP2 are used for typing. Interpretation of the results is, however, complicated due to possible recombination events between the VP4 and VP1 genomic parts. Next generation sequencing is used for sequencing the complete enterovirus genomes. In most cases, the complete genomic sequence is not relevant in diagnosing individual patients, but it gives important information e.g., on the emergence of new outbreak strains, recombinant types and evolutionary history.

Although largely replaced by molecular assays in primary diagnostics, the golden standard in enterovirus diagnostics – isolation in cell culture – is used in national enterovirus/poliovirus laboratories globally. Most enteroviruses grow rapidly in continuous monkey and human cell lines. The typical cytopathic effect (CPE) appears in 2 to 3 days after inoculation, negative samples are followed for at least 10 days. The CPE is not specific for enteroviruses and the virus isolate should be confirmed as an enterovirus by a real-time PCR assay, sequencing or neutralization with type-specific antisera or pools made of them.

Enterovirus-specific IgM and IgG antibodies are measured by commercial or in-house EIA assays. IgM antibodies are indicative of a recent symptomatic or asymptomatic infection. The IgG antibodies are determined from acute and convalescent sera, and a significant increase is an indication of an acute or very recent infection. The antigen in the IgM and IgG assays is mostly a mixture of VP1 antigens from multiple enterovirus types and gives group-specific, not type-specific results. In addition to IgM- and IgG-EIA, neutralizing antibodies can be measured against a specific virus type in a cell culture assay. The positivity is a reliable indication of a past infection – two serum specimens are needed for the detection of a rise or decline in titers to predict a recent infection. Although not practical in rapid diagnostics, both antibody assays are used widely in seroprevalence studies where large populations are screened for their infection history.

Treatment

In general, enterovirus infections are cleared by host immune system in few days or at least in weeks. Anti-enteroviral drugs have not yet been approved for clinical use. The treatment of enterovirus disease is symptomatic and aims to prevent complications. Immune-modulating treatments, such as intravenous immunoglobulin (IVIG), have been used in severe neonatal cases, hypogammaglobulinemia patients and disease outbreaks, but the evidence of benefits is not conclusive. However, there is supporting evidence that early administered IVIG may reduce the risk of autonomic nervous system dysregulation and death in severe EV-A71 infections, and the treatment is recommended by the WHO. The other passive immunotherapy options are high-dose corticosteroids, plasmapheresis and convalescent serum.

The need for broad-reactive, efficient and safe anti-enteroviral drugs is obvious and has led to an active development during the past decades. Some drugs have been tested in clinical trials but either the lack of efficiency or the emergence of side effects has prevented their licensing for clinical use.

Any step of the enterovirus life cycle may be a target for antiviral therapy. The antivirals can affect the functions of either virus proteins or host factors essential to viral infection. The side effects are supposed to be less prominent if the goal is the virus itself, but targeting the virus may soon result in the emerge of drug-resistant virus strains. The drug candidates are screened from compound libraries and optimized chemically or synthesized *de novo*. As a new approach, drug repurposing is performed to screen for compounds that have already been proved to be safe and that are used in treatment of other diseases.

So far the most promising antivirals have been capsid binders, which occupy the hydrophobic pocket in the capsid and interfere with receptor binding and uncoating by stabilizing the virus particle. The capsid binders can be either pan-enteroviral with broad specificity or targeted to a single type, e.g., EV-A71. In clinical trials, for example Pleconaril, Pirodavidir, Vapendavidir and Pocapavidir have shown efficiency in inhibiting some enteroviruses, but not all types. The fast emergence of resistant viruses was also noticed.

Promising targets have also been viral proteases 2A and 3C, which are involved in viral polyprotein processing. Rupintrivir targets the active site of 3C and inhibits rhinovirus and EV-A71 infection. Viral replication can be affected by inhibiting the 3D polymerase. This can be done either by using nucleoside analogs such as ribavirin and gemcitabine or non-nucleoside inhibitors like amiloride. 2C inhibitors have also been described, one of them being drug fluoxetine.

Virus replication needs essential host factors, which may also be the targets for antivirals. For example, enviroxime, which is an inhibitor of phosphatidylinositol 4-kinase- β , was effective against all enterovirus species in clinical trials, but the drug caused adverse side effects.

Prevention

The most effective prevention of enterovirus infection is achieved by good hygiene, which interrupts the transmission of the virus. Enteroviruses are spread in droplets by coughing and sneezing and they are excreted in feces. In addition, depending on the clinical picture, enteroviruses may be present in eye secretions and blisters. The guidelines emphasize the need for hand washing with soap and water as alcohol-based disinfectants do not have an effect on enteroviruses. Contaminated surfaces should be washed with chlorine or soap and water.

Enterovirus diseases could be prevented efficiently with vaccines, as shown by almost completed eradication of polioviruses. Both inactivated poliovirus vaccine (IPV) and live, attenuated oral vaccine (OPV) have been safe and efficient in preventing poliomyelitis and diminishing virus circulation. The experience on the poliovirus vaccines is of great value when developing new vaccines against other enteroviruses. The major disadvantage of IPV is the weak prevention of transmission, which is better obtained by OPV, which induces better mucosal immunity. The disadvantage of OPV is the reversion of attenuated poliovirus strains to neurovirulent mutants, which may occasionally cause vaccine associated poliomyelitis or, in certain epidemiological situations, circulation of vaccine-derived polioviruses.

Designing a broad-spectrum vaccine against many or all enterovirus types has been too challenging so far. However, attempts have been made to develop vaccines against prevalent enterovirus types such as EV-A71. The first formalin-inactivated whole-virus vaccine against EV-A71 was approved by the Food and Drug Administration of China in 2015. The second vaccine was licensed in 2016, and further products are in clinical trials at the moment. The EV-A71 strains used in the first two vaccines are from different origin, but they both belong to sub-genotype C4a, which has been the most important virus type in Chinese outbreaks. Phase III clinical trials have involved over 30,000 infants and showed that the vaccines are safe and can prevent over 90% of EV-A71-associated HFMD or herpangina.

Besides inactivated and live-virus-vaccines, attenuated whole-virus vaccines are under development against some other EV types as well. Other potential vaccine constructs include virus-like particles, recombinant proteins and DNA vaccines.

Glossary

3CL^{pro} or M^{pro} 3C-like proteinase, or main proteinase.

ADRP ADP-ribose-1''-phosphatase.

CS TRS Core sequence.

ExoN 3' to 5' exoribonuclease.

NendoU Nidovirus endoribonuclease.

O-MT Ribose-2'-O-methyltransferase.

PL^{pro} Papain-like cysteine proteinase.

TRS Transcription-regulating sequence.

Taxonomy and Phylogeny

The order *Nidovirales* includes the families *Coronaviridae*, *Roniviridae*, and *Arteriviridae* (Fig. 1). The *Coronaviridae* comprises two well-established genera, *Coronavirus* and *Torovirus*, and a tentative new genus, *Bafinivirus*. The *Arteriviridae* and *Roniviridae* include only one genus each, *Arterivirus* and *Okavirus*, respectively. All nidoviruses have single-stranded RNA genomes of positive polarity that, in the case of the *Corona*- and *Roniviridae* (26–32 kbp), are the largest presently known RNA virus genomes. In contrast, members of the *Arteriviridae* have a smaller genome ranging from about 13 to 16 kbp. The data available from phylogenetic analysis of the highly conserved RNA-dependent RNA polymerase (RdRp) domain of these viruses, and the collinearity of the array of functional domains in nidovirus replicase polyproteins, were the basis for clustering coronaviruses and toroviruses (Fig. 2). The more distantly related roniviruses also group with corona- and toroviruses, thus forming a kind of supercluster of nidoviruses with large genomes. By contrast, arteriviruses must have diverged earlier during nidovirus evolution. The current taxonomic position of coronaviruses and toroviruses as two genera of the family *Coronaviridae* is currently being revised by elevating these virus groups to the taxonomic rank of either subfamily or family.

A comparative sequence analysis of coronaviruses reveals three phylogenetically compact clusters: groups 1, 2, and 3. Within group 1, two subsets can be distinguished: subgroup 1a that includes transmissible gastroenteritis virus (TGEV), canine coronavirus (CCoV), and feline coronavirus (FCoV), and subgroup 1b that includes the human coronaviruses (HCoV) 229E and NL63, porcine epidemic diarrhoea virus (PEDV), and bat coronavirus (BtCoV) 512 which was isolated in 2005. Within group 2 coronaviruses, two subsets have been recognized: subgroup 2a, including mouse hepatitis virus (MHV), bovine coronavirus (BCoV), HCoV-OC43, and HCoV-HKU1; and subgroup 2b, including severe acute respiratory syndrome coronavirus (SARS-CoV) and its closest circulating bat coronavirus relative, BtCoV-HKU3. A growing number of other bat viruses has been recently identified in groups 1 and 2. It is currently being debated whether some of these viruses (e.g., BtCoV-HKU5, BtCoV-133 (isolated in 2005), and BtCoV-HKU9) may in fact represent novel subgroups or groups. Avian infectious bronchitis virus (IBV) is the prototype of coronavirus group 3, which also includes several other bird coronaviruses. In arteriviruses, there are four comparably distant genetic clusters, the prototypes of which are equine arteritis virus (EAV), lactate dehydrogenase-elevating virus (LDV) of mice, simian hemorrhagic fever virus (SHFV) infecting monkeys, and porcine reproductive and respiratory syndrome virus (PRRSV) which infects pigs and includes European and North American genotypes.

Roniviruses are the only members of the order *Nidovirales* that are known to infect invertebrates. The family *Roniviridae* includes the penaeid shrimp virus, gill-associated virus (GAV), and the closely related yellow head virus (YHV).

More than 100 full-length coronavirus genome sequences and around 30 arterivirus genome sequences have been documented so far, whereas only very few sequences have been reported for toroviruses, bafiniviruses, and roniviruses. Therefore, information on the genetic variability of these nidovirus *taxa* is limited.

Diseases Associated with Nidoviruses

Coronavirus infections are mainly associated with respiratory, enteric, hepatic, and central nervous system diseases. In humans and fowl, coronaviruses primarily cause upper respiratory tract infections, while porcine and bovine coronaviruses establish enteric

Fig. 1 Nidovirus classification and prototype members. The order *Nidovirales* containing the families *Coronaviridae* (including the established genera *Coronavirus* and *Torovirus*, and a new tentative genus *Bafinivirus*), *Arteriviridae*, and *Roniviridae*. Phylogenetic analysis (see Fig. 2) has confirmed the division of coronaviruses into three groups. In arteriviruses, four comparably distant genetic clusters have been differentiated. To facilitate the taxonomy of the different virus isolates, the types Co, To, Ba, Ro, standing for coronavirus, torovirus, bafinivirus, or ronivirus, respectively, have been included. The following CoVs are shown: human coronaviruses (HCoV) 229E, HKU1, OC43 and NL63, transmissible gastroenteritis virus (TGEV), feline coronavirus (FCoV), porcine epidemic diarrhoea virus (PEDV), mouse hepatitis virus (MHV), bovine coronavirus (BCoV), bat coronaviruses (BtCoV) HKU3, HKU5, HKU9, 133 and 512 (the last two isolated in 2005), porcine hemagglutinating encephalomyelitis virus (PHEV), avian infectious bronchitis virus (IBV), and severe acute respiratory syndrome coronavirus (SARS-CoV); ToV: equine torovirus (EToV), bovine torovirus (BTov), human torovirus (HToV), and porcine torovirus (PToV); BaV: white bream virus (WBV); Arterivirus: equine arteritis virus (EAV), simian haemorrhagic fever virus (SHFV), lactate dehydrogenase-elevating virus (LDV), and three (Euro, HB1, and MLV) porcine reproductive and respiratory syndrome viruses (PRRSV); RoV: gill-associated virus (GAV) and yellow head virus (YHV). Human viruses are highlighted in red. Some nodes are formed by a pair of very closely related viruses (e.g., SARS-CoV and BtCoV-HKU3). Asterisk indicates tentative genus.

infections, often resulting in severe economic losses. In 2002, a previously unknown coronavirus that probably has its natural reservoir in bats crossed the species barrier and caused a major outbreak of SARS, which led to more than 800 deaths worldwide.

Toroviruses cause gastroenteritis in mammals, including humans, and possibly also respiratory infections in older cattle. Bafiniviruses have been isolated from white bream fish but there is currently no information on the pathogenesis associated with this virus infection. Roniviruses usually exist as asymptomatic infections but can cause severe disease outbreaks in farmed black tiger shrimp (*Penaeus monodon*) and white pacific shrimp (*Penaeus vannamei*), which in the case of YHV can result in complete crop losses within a few days after the first signs of disease in a pond. Infections by arteriviruses can cause acute or persistent asymptomatic infections, or respiratory disease and abortion (EAV and PRRSV), fatal age-dependent poliomyelitis (LDV), or fatal hemorrhagic fever (SHFV). Arteriviruses, particularly PRRSV in swine populations, cause important economic losses.

Virus Structure

In addition to the significant variations in genome size among the three nidovirus families mentioned above, there are also major differences in virion morphology (Fig. 3) and host range. Nidoviruses have a lipid envelope which protects the internal nucleocapsid structure and contains a number of viral surface proteins (Fig. 3). Whereas coronaviruses and the significantly smaller arteriviruses have spherical particle structures, elongated rod-shaped structures are observed in toro-, bafini-, and ronivirus-infected cells. The virus particles of the *Corona*- and *Roniviridae* family members carry large surface projections that protrude from the viral envelope (peplomers), whereas arterivirus particles possess only relatively small projections on their surface. Coronaviruses have an internal core shell that is formed by a nucleocapsid featuring a helical symmetry. The nucleocapsid (N) protein interacts with the carboxy-terminus of the envelope membrane (M) protein. The intracellular forms of torovirus, bafinivirus, and ronivirus

Fig. 2 Nidovirus phylogeny. Tree depicting the evolutionary relationships between the five major groups of nidoviruses as shown in Fig. 1 (Coronavirus, Torovirus, Bafinivirus, Ronivirus, and Arterivirus). This unrooted maximum parsimonious tree was inferred using multiple nucleotide alignments of the RdRp-HEL region of a representative set of nidoviruses with the help of the PAUP*v.4.0b10 software (AEG, unpublished). Support for all bifurcations from 100 bootstraps performed is indicated. The phylogenetic distances shown are approximate. For acronyms, see Fig. 1.

nucleocapsids have extended rod-shaped (helical) morphology. By contrast, mature (extracellular) toroviruses (but not bafini- and roniviruses) feature a remarkable structural flexibility, which allows them to adopt crescent- and toroid-shaped structures also. Unlike other nidoviruses, arteriviruses have an isometric core shell. In all nidoviruses, the nucleocapsid is formed by only a single N protein that interacts with the genomic RNA.

Both the number and properties of structural proteins vary between viruses of the three families of the *Nidovirales* and may even vary among viruses of the same family. Nidoviruses usually encode at least three structural proteins: a spike (S) or major surface glycoprotein, a trans-membrane (M) or matrix protein, and the N protein (Fig. 3). Ronivirus particles are unique in that they possess two envelope glycoproteins, gp116 (S1) and gp64 (S2), but no M protein. Coronavirus and arterivirus particles possess another envelope protein called E that is not conserved in toroviruses, bafini-, and roniviruses. Toroviruses and subgroup 2a coronaviruses, such as MHV, have a hemagglutinin esterase (HE) as an additional structural protein, whereas the SARS-CoV has at least four additional proteins that are present in the viral envelope (encoded by ORFs 3a, 6, 7a, and 7b). The proteins may promote virus growth in cell culture or *in vivo*, but they are dispensable for virus replication.

The major envelope proteins are the S and M proteins in coronaviruses and toroviruses, the GP₅ and M proteins in arteriviruses, and the S1 and S2 proteins in roniviruses. Among these, only the corona-, toro-, and bafinivirus S and M proteins share limited sequence similarities, possibly indicating a common origin. Whereas S proteins can differ in size, they share an exposed globular head domain and, with the exception of roniviruses, a stem portion containing heptad repeats organized in a coiled-coil structure. The S proteins of corona- and toroviruses (and most likely those of bafiniviruses) form trimers that bind the cell surface receptor whereas receptor binding in roniviruses is probably mediated by gp116 (S1). The arterivirus envelope proteins form two higher-order complexes: one is a disulfide-linked heterodimer of GP₅ and the M protein; and the other is a heterotrimer of the minor structural glycoproteins GP₂, GP₃, and GP₄. Except for the E and M proteins, all arterivirus structural proteins are glycosylated. By contrast, the M proteins of corona- and toroviruses (and, most likely, bafiniviruses) are glycosylated, and they share a triple-spanning membrane topology with the amino-terminus exposed on the outside of the virions and the carboxy-terminus facing the nucleocapsid. In TGEV, a proportion of the M proteins has a tetra-spanning membrane topology leading to the exposure of both termini on the virion surface.

In the virion, the coronavirus E protein has a low copy number (around 20) and deletion of the E protein gene from the genome of the group 1 coronavirus TGEV blocks virus maturation, preventing virus release and spread. In the group 2 coronaviruses MHV and SARS-CoV, deletion of the E protein results in a dramatic reduction, of up to 100 000-fold, of virus infectivity. The coronavirus E and SARS-CoV 3a proteins are viroporins, that is, they belong to a group of proteins that modify membrane permeability by forming ion channels in the virion envelope.

Fig. 3 Nidovirus structure. Architecture of particles of members of the order *Nidovirales*: electron micrographs (a) and schematic representations (b) are shown. N, nucleocapsid protein; S, spike protein; M, membrane protein; E, envelope protein; HE, hemagglutinin-esterase. Coronavirus M protein interacts with the N protein. In arterivirus, GP₅ and M are major envelope proteins, while GP₂, GP₃, GP₄, and E are minor envelope proteins. Toro-, bafini-, and roniviruses lack the E protein present in corona- and arteriviruses. Proteins gp116 and gp64, ronivirus envelope proteins. Different images were reproduced with permission from different authors: arterivirus, E. Snijder (Leiden, The Netherlands); ronivirus, P. J. Walker (CSIRO, Australia); bafinivirus, J. Ziebuhr (Queen's University, Belfast) torovirus, D. Rodriguez (CNB, Spain); coronavirus, L. Enjuanes (CNB, Spain).

Genome Organization

Nidovirus genomes contain variable numbers of genes, but in all cases the 5' terminal two-thirds to three-quarters of the genome is dedicated to encoding the key replicative proteins, whereas the 3' proximal genome regions generally encode the structural and, in some cases, accessory (group- and virus-specific) proteins (Fig. 4). Nidovirus genome expression is controlled at the translational and post-translational levels. Thus, for example, ribosomal frameshifting is required for the expression of ORF1b, and the two replicase polyproteins (pp1a and pp1ab) are proteolytically processed by viral proteases. The proteolytic processing occurs in a

Fig. 5 Nidovirus replicase genes. Polyprotein (pp) 1ab domain organizations are shown for representative viruses from the five nidovirus genera. Acronyms as in Fig. 1. Arterivirus and coronavirus pp1ab processing pathways have been characterized in considerable detail and are illustrated here for EAV and MHV. N-proximal polyprotein regions are cleaved at two or three sites by viral papain-like proteases 1 (PL1) and 2 (PL2), whereas the central and C-terminal polyprotein regions are processed by the main protease, M^{pro}. PL1 domains are indicated by orange boxes and cognate cleavage sites are indicated by orange arrowheads. PL2 domains and PL2-mediated cleavages are shown in green and CL domains and CL-mediated cleavages are shown in red. Note that EAV encodes a second, but proteolytically inactive PL1 domain (PL1*; orange-striped box). For the genera *Torovirus*, *Bafinivirus*, and *Okavirus*, the available information on pp1ab proteolytic processing is limited and not shown here. Other predicted or proven enzymatic activities are shown in blue: ADRP, ADP-ribose 1'-phosphatase; Rps, noncanonical RNA polymerase ('primase') activity; RdRp, RNA-dependent RNA polymerase; HEL, NTPase/RNA helicase and RNA 5'-triphosphatase; ExoN, 3'-to-5' exoribonuclease; NendoU, nidoviral uridylyte-specific endoribonuclease; MT, ribose-2'-O methyltransferase; CPD, cyclic nucleotide phosphodiesterase. Regions with predicted transmembrane (TM) domains are indicated by gray boxes. Other functional domains are shown as white boxes: Ac, acidic domain; Y, Y domain containing putative transmembrane and zinc-binding regions; ZBD, helicase-associated zinc-binding domain; RBPs, RNA-binding proteins. Expression of the C-terminal part of pp1ab requires a ribosomal frameshift, which occurs just upstream of the ORF1a translation stop codon. The ribosomal frameshift site (RFS) is indicated.

to develop selective protease inhibitors that block viral replication, suggesting that nidovirus main proteases may be attractive targets for antiviral drug design.

In arteri-, corona-, and toroviruses, the M^{pro} is assisted by 1–4 papain-like ('accessory') proteases (PL^{pro}) that process the less well-conserved N-proximal region of the replicase polyproteins (Fig. 5). Nidovirus PL^{pro} domains may include zinc ribbon structures and some of them have deubiquitinating activities, suggesting that these proteases might also have functions other than polyprotein processing. Bafini- and roniviruses have not been studied in great detail and it is not yet clear if these viruses employ papain-like proteases to process their N-terminal pp1a/pp1ab regions (Fig. 5).

The replicase polyproteins of 'large' nidoviruses with genome sizes of more than 26 kb (i.e., corona-, toro-, bafini-, and roniviruses) include 3'-5' exoribonuclease (ExoN) and ribose-2'-O-methyltransferase (MT) activities that are essential for coronavirus RNA synthesis but are not conserved in the much smaller arteriviruses (Fig. 5). The precise biological function of ExoN has not been established for any nidovirus but the relationship with cellular DEDD superfamily exonucleases and recently published data suggest that ExoN may have functions in the replication cycle of large nidoviruses that, like in the DEDD homologs, are related to proofreading, repair, and recombination mechanisms.

NendoU is a nidovirus-wide conserved domain that has no counterparts in other RNA viruses. It is therefore considered a genetic marker of the *Nidovirales*. The endonuclease has uridylyte specificity and forms hexameric structures with six independent catalytic sites. Cellular homologs of NendoU have been implicated in small nucleolar RNA processing whereas the role of NendoU in viral replication is less clear. Reverse genetics data indicate that NendoU has a critical role in the viral replication cycle.

Two other RNA-processing domains, ADP-ribose-1''-phosphatase (ADRP) and nucleotide cyclic phosphodiesterase (CPD), are conserved in overlapping subsets of nidoviruses (Fig. 5). Except for arteri- and roniviruses, all nidoviruses encode an ADRP domain that is part of a large replicase subunit (nsp3 in the case of coronaviruses). The coronavirus ADRP homolog has been shown to have ADP-ribose-1'-phosphatase and poly(ADP-ribose)-binding activities. Although the highly specific phosphatase activity is not essential for viral replication *in vitro*, the strict conservation in all genera of the *Coronaviridae* suggests an important (though currently unclear) function of this protein in the viral replication cycle. This may be linked to host cell functions and,

Fig. 6 SARS-CoV genome organization and sg mRNA expression. A diagram of CoV structure using SARS-CoV as a prototype. Below the top bar a set of positive- and negative-sense mRNA species synthesized in infected cells is shown. Dark and light blue lines (+), mRNA sequences translated and nontranslated into viral proteins, respectively. Light gray lines (–), RNAs complementary to the different mRNAs. L, leader sequence. Poly(A) and Poly(U) tails are indicated by AAA or UUU, respectively. Rep 1a and Rep 1b, replicase genes. Other acronyms above and below the top bar indicate structural and nonstructural proteins. Numbers and letters to the right of the thin bars indicate the sg mRNAs.

particularly, to the activities of cellular homologs called ‘macro’ domains which are thought to be involved in the metabolism of ADP-ribose and its derivatives.

The CPD domain is only encoded by toroviruses and group 2a coronaviruses. In toroviruses, the CPD domain is encoded by the 3′ end of replicase ORF1a (Fig. 5), whereas in group 2a coronaviruses, the enzyme is expressed from a separate subgenomic RNA. The enzyme’s biological function is not clear. Coronavirus CPD mutants are attenuated in the natural host whereas replication in cell culture is normal, suggesting some function *in vivo*. The available information suggests that nidovirus replicase polyproteins (particularly, those of large nidoviruses) have evolved to include a number of nonessential functions that may provide a selective advantage in the host.

ORF1a of all nidoviruses encodes a number of (putative) transmembrane proteins, like the coronavirus nsps 3, 4, and 6 and the arterivirus nsps 2, 3, and 5. These have been shown or postulated to trigger the modification of cytoplasmic membranes, including the formation of unusual double-membrane vesicles (DMVs). Tethering of the replication–transcription complex to these virus-induced membrane structures might provide a scaffold or subcellular compartment for viral RNA synthesis, possibly allowing it to proceed under conditions that prevent or impair detection by cellular defense mechanisms, which are usually induced by the double-stranded RNA intermediates of viral replication.

Finally, recent structural and biochemical studies have yielded novel insights into the function of a set of small nsps encoded in the 3′-terminal part of the coronavirus ORF1a. For example, nsp7 and nsp8 were shown to form a hexadecameric supercomplex that is capable of encircling dsRNA. The coronavirus nsp8 was also shown to have RNA polymerase (primase) activity that may produce the primers required by the primer-dependent RdRp residing in nsp12. For nsp9 and nsp10, RNA-binding activities have been demonstrated and crystal structures have been reported for both proteins. Nsp10 is a zinc-binding protein that contains two zinc-finger-binding domains and has been implicated in negative-strand RNA synthesis.

Structural and Accessory Protein Genes

In contrast to the large genome of *Coronaviridae*, which can accommodate genes encoding accessory proteins (i.e., proteins called ‘nonessential’ for being dispensable for replication in cell culture (Fig. 6)), the smaller genomes of arteriviruses only encode essential proteins (Fig. 4). Coronaviruses encode a variable number of accessory proteins (2–8), while the torovirus genome contains a single accessory gene encoding a hemagglutinin-esterase (HE). Coronavirus accessory genes may occupy any intergenic position in the conserved array of the four genes encoding the major structural proteins (5′-S-E-M-N-3′), or they may reside upstream or downstream of this gene array. Roniviruses are unique among the presently known nidoviruses in that the gene encoding the N protein is located upstream rather than downstream of the gene encoding the glycoproteins. Several members of the coronavirus group 1a are exceptional in that they contain genes downstream of the N protein gene, which has not been reported for other coronaviruses. The ronivirus glycoprotein gene is also unique in that it encodes a precursor polyprotein with two

internal signal peptidase cleavage sites used to generate the envelope glycoproteins S1 and S2 as well as an amino-terminal protein with an unknown function.

The accessory genes are specific for either a single virus species or a few viruses that form a compact phylogenetic cluster. Many proteins encoded by accessory genes may function in infected cells or *in vivo* to counteract host defenses and, when removed, may lead to attenuated virus phenotypes. Group 1 coronaviruses may have 2–3 accessory genes located between the S and E genes and up to two other genes downstream of N gene. Viruses of group 2 form the most diverse coronavirus cluster, and they may have between three and eight accessory genes. In this cluster, MHV, HCoV-OC43, and BCoV form the phylogenetically compact subgroup, 2a, that is characterized by the presence of (1) two accessory genes located between ORF1b and the S gene encoding proteins with CPD and HE functions, (2) two accessory genes located between the S and E protein genes, and (3) an accessory gene, I, that is located within the N protein gene. Of this set of five accessory proteins, only three homologs are encoded by the recently identified HCoV-HKU1, which is the closest known relative of the cluster formed by MHV, HCoV-OC43, and BCoV. In contrast, the most distant group 2 member, SARS-CoV, has seven or eight unique accessory genes, two between the S and E protein genes, four to five between the M and N protein genes, and ORF9b which entirely overlaps with the N protein gene in an alternative reading frame. In group 3 avian coronaviruses, of which IBV is the prototype, several accessory genes, which are expressed from functionally tri- or bicistronic mRNAs, have been identified in the region between the S and E protein genes (gene 3) and between the M and N protein genes (gene 5).

Some functionally dispensable ORF1a-encoded replicase domains may also be considered as accessory protein functions. For instance, MHV and SARS-CoV nsp2 turned out to be nonessential for replication in cell culture.

Replication

Like in all other positive-stranded RNA viruses, nidovirus genome replication is mediated through the synthesis of a full-length, negative-strand RNA which, in turn, is the template for the synthesis of progeny virus genomes. This process is mediated by the viral replication complex that includes all or most of the 14–16 nsps derived from the proteolytic processing of the pp1a and pp1ab replicase polyproteins of arteriviruses and coronaviruses. The replication complex, which is likely to include also cellular proteins, is associated with modified intracellular membranes, which may be important to create a microenvironment suitable for viral RNA synthesis as well as for recruitment of host factors. Electron microscopy studies of cells infected with arteriviruses (EAV) and coronaviruses (MHV and SARS-CoV) have shown that RNA synthesis is associated with virus-induced, DMVs. The origin of DMVs is under debate and different intracellular compartments including the Golgi, late endosomal membranes, autophagosomes, and the endoplasmic reticulum have been implicated in their formation.

Studies of *cis*-acting sequences required for nidovirus replication have mainly relied on coronavirus defective-interfering (DI) RNAs replicated by helper virus. Genome regions harboring minimal *cis*-acting sequences have been mapped to around 1 kb domains of the genomic 5' and 3' ends. Studies with MHV DI RNAs have indicated that both genome ends are necessary for positive-strand synthesis, whereas only the last 55 nt and the poly (A) tail at the genomic 3' end are required for negative-strand synthesis. It has been postulated that the 5' and 3' ends of the genome may interact directly during RNA replication, as predicted by computer-aided simulations of MHV and TGEV genomic RNA interactions in protein-free media. There is, however, some experimental evidence supporting protein-mediated cross-talk between both genome ends in the form of RNA–protein and protein–protein interactions.

Several experimental approaches have implicated, in addition to the nsps encoded by the replicase gene, the N protein in coronavirus RNA synthesis. Early in infection, the coronavirus N protein colocalizes with the site of viral RNA synthesis. In addition, the N protein can enhance the rescue of various coronaviruses from synthetic full-length RNA, transcribed *in vitro* or from cDNA clones. In contrast, arterivirus RNA synthesis does not require the N protein.

Host factors that may participate in nidovirus RNA synthesis have been identified mainly from studies of coronaviruses and arteriviruses. In coronaviruses (MHV and TGEV), heterogeneous nuclear ribonucleoprotein (hnRNP) A1 has been identified as a major protein binding to genomic RNA sequences complementary to those in the negative-strand RNA that bind another cellular protein, polypyrimidine tract-binding protein (PTB). hnRNP A1 and PTB bind to the complementary strands at the 5' end of coronavirus RNA and could mediate the formation of an RNP replication complex involving the 5' and 3' ends of coronavirus genomic RNA. The functional relevance of hnRNP A1 in coronavirus replication was supported by experiments showing that its overexpression promotes MHV replication, whereas replication was reduced in cells expressing a dominant-negative mutant of hnRNP A1. There is also experimental evidence to suggest that the poly(A)-binding protein (PABP) specifically interacts with the 3' poly(A) tail of coronavirus genomes, and that this interaction may affect their replication. Other cellular proteins found to bind to coronavirus genomic RNA, such as aconitase and the heat shock proteins HS40 and HS70, might be involved in modulating coronavirus replication. Similarly, interactions of cellular proteins such as transcription cofactor p100 with the EAV nsp1, or of PTB or fructose biphosphate aldolase A with SHFV genomic RNA, suggest that, in arterivirus replication also, a number of cellular proteins may be involved.

Transcription

RNA-dependent RNA transcription in some members of the *Nidovirales* (coronaviruses, bafiniviruses, and arteriviruses), but not in others (roniviruses), includes a discontinuous RNA-synthesis step. This process occurs during the production of subgenome-length

negative-strand RNAs that serve as templates for transcription and involves the fusion of a copy of the genomic 5'-terminal leader sequence to the 3' end of each of the nascent RNAs complementary to the coding (body) sequences (Fig. 6). The resulting chimeric sg RNAs of negative polarity are transcribed to yield sg mRNAs that share both 5'- and 3'- terminal sequences with the genome RNA. Genes expressed through sg mRNAs are preceded by conserved 'transcription-regulatory sequences' (TRSs) that presumably act as attenuation or termination signals during the production of the subgenome-length negative-strand RNAs. In arteriviruses and coronaviruses, the TRSs preceding each ORF are presumed to direct attenuation of negative-strand RNA synthesis, leading to the 'jumping' of the nascent negative-strand RNA to the leader TRS (TRS-L). This process is guided by a base-pairing interaction between complementary sequences (leader TRS and body TRS complement) and it has been proposed that template switching only occurs if the free energy (ΔG) for the formation of this duplex reaches a minimum threshold. This process is named 'discontinuous extension of minus strands' and can be considered a variant of similarity-assisted template-switching that operates during viral RNA recombination. The genome and sg mRNAs share a 5'-leader sequence of 55–92 nt in coronaviruses and 170–210 nt in arteriviruses.

Toroviruses are remarkable in that they employ a mixed transcription strategy to produce their mRNAs. Of their four sg mRNA species, the smaller three (mRNAs 3 through 5) lack a 5' common leader and are produced via nondiscontinuous RNA synthesis. In contrast, sg mRNA2 has a leader sequence that matches the 5'-terminal 18 nt of the genomic RNA and its production requires a discontinuous RNA-synthesis step reminiscent of, but not identical, to that seen in arteri- and coronaviruses.

Synthesis of torovirus mRNAs 3 through 5, and possibly of the two mRNAs in roniviruses, is thought to require the premature termination of negative-strand RNA synthesis at conserved, intergenic, TRS-like sequences to generate subgenome-length negative-strand RNAs that can be used directly as templates for sg mRNA synthesis. In the case of torovirus mRNA2, a TRS is lacking. Fusion of noncontiguous sequences seems to be controlled by a sequence element consisting of a hairpin structure and 3' flanking stretch of 23 residues with sequence identity to a region at the 5' end of the genome. It is thought that during negative-strand synthesis, the hairpin structure may cause the transcriptase complex to detach, prompting a template switch similar to that seen in arteri- and coronaviruses.

In addition to regulatory RNA sequences, viral and host components involved in protein–RNA and protein–protein recognition are likely to be important in transcription. For example, the arterivirus nsp1 protein has been identified as a factor that is dispensable for genome replication but absolutely required for sg RNA synthesis. The identification of host factors participating in nidovirus transcription is a field under development and specific binding assays have recently identified a limited number of cellular proteins that associate with *cis*-acting RNA regulatory sequences. For example, differences in affinity of such factors for body TRSs might regulate transcription in nidoviruses by a mechanism similar to that of the DNA-dependent RNA-polymerase I termination system, in which specific proteins bind to termination sequences.

Origin of Nidoviruses

The complex genetic plan and the replicase gene of nidoviruses must have evolved from simpler ones. Using this natural assumption, a speculative scenario of major events in nidovirus evolution has been proposed. It has been speculated that the most recent common ancestor of the *Nidovirales* had a genome size close to that of the current arteriviruses. This ancestor may have evolved from a smaller RNA virus by acquiring the two nidovirus genetic marker domains represented by the helicase-associated zinc-binding domain (ZBD) and the NendoU function. These two domains may have been used to improve the low fidelity of RdRp-mediated RNA replication, thus generating viruses capable of efficiently replicating genomes of about 14 kbp. The subsequent evolution of much larger nidovirus genomes may have been accompanied by the acquisition of the ExoN domain. This domain may have further improved the fidelity of RNA replication through its 3'–5' exonuclease activity, which might operate in proofreading mechanisms similar to those employed by DNA-based life forms. It has been suggested that the ORF1b-encoded HEL, ExoN, NendoU, and O-MT domains may provide RNA specificity, whereas the relatively abundantly expressed CPD and ADRP might control the pace of a common pathway that could be part of a hypothetical oligonucleotide-directed repair mechanism used in the present coronaviruses and roniviruses. The expansion of the replicase gene may have been associated with an increase in replicase fidelity, thus also supporting the further expansion of the 3'-proximal genome region to encode the structural proteins required to form complex enveloped virions.

Effect of Nidovirus Infection on the Host Cell

Compared to other viruses, the interactions of nidoviruses with their hosts have not been studied in great detail. In many cases, information is based on relatively few studies performed on a limited number of viruses from the families *Coronaviridae* and *Arteriviridae*. Also, most studies have been performed with viruses that have been adapted to cell culture and therefore may have properties that differ from those of field strains. Coronaviruses and arteriviruses are clearly the best-studied members of the *Nidovirales* in terms of their interactions with the host.

Coronavirus infection affects cellular gene expression at the level of both transcription and translation. Upon infection, host cell translation is significantly suppressed but not shut off, as is the case in several other positive-RNA viruses. The underlying mechanisms have not been characterized in detail, but data obtained for MHV and BCoV suggest that they may involve the 5'-leader sequences present on coronavirus mRNAs. The viral N protein was reported to bind to the 5'-common leader sequence and

it has been speculated that this might promote translation initiation, leading to a preferential translation of viral mRNAs. Furthermore, host mRNAs were reported to be specifically degraded in MHV- and SARS-CoV-infected cells, further reducing the synthesis of cellular proteins. Another mechanism affecting host cell protein synthesis may be based on specific cleavage of the 28S rRNA subunit, which was observed in MHV-infected cells.

Studies on cellular gene expression following nidovirus infections have mainly focused on the coronaviruses MHV and SARS-CoV. For example, SARS-CoV infection was reported to disrupt cellular transcription to a larger extent than does HCoV-229E. Differences in cellular gene expression have been proposed to be linked to differences in the pathogenesis caused by these two human coronaviruses. Apart from the downregulation of genes involved in translation and cytoskeleton maintenance, genes involved in stress response, proapoptotic, proinflammatory, and procoagulating pathways were significantly upregulated. Both MHV and SARS-CoV induce mitogen-activated phosphate kinases (MAPKs), especially p38 MAPK. In addition, activation of AP-1, nuclear factor kappa B (NF- κ B), and a weak induction of Akt signaling pathways occur after SARS-CoV infection and the N and nsp1 proteins were suggested to be directly involved in inducing these signaling pathways.

Nidoviruses have also been reported to interfere with cell cycle control. Infection by the coronaviruses TGEV, MHV, SARS-CoV, and IBV was reported to cause a cell cycle arrest in the G0/G1 phase and a number of cellular proteins (e.g., cyclin D3 and hypophosphorylated retinoblastoma protein) and viral proteins (MHV nsp1, SARS-CoV 3b 7a, and N proteins) have been proposed to be involved in the cell cycle arrest in G0/G1.

Many viruses encode proteins that modulate apoptosis and, more generally, cell death, which allows for highly efficient viral replication or the establishment of persistent infections. Infection by coronaviruses (e.g., TGEV, MHV, and SARS-CoV) and arteriviruses (e.g., PRRSV and EAV) have been reported to induce apoptosis in certain cell types. Apoptosis has also been reported in shrimp infected with the ronavirus YHV and is thought to be involved in pathogenesis. Both apoptotic and antiapoptotic molecules have been found to be upregulated, suggesting that a delicate counterbalance of pro- and antiapoptotic molecules is required to ensure cell survival during the early phase of infection, and rapid virus multiplication before cell lysis occurs. Coronavirus-induced apoptosis appears to occur in a tissue-specific manner, which obviously has important implications for viral pathogenesis. For instance, SARS-CoV was shown to infect epithelial cells of the intestinal tract and induce an antiapoptotic response that may counteract a rapid destruction of infected enterocytes. These findings are consistent with clinical observations of a relatively normal endoscopic and microscopic appearance of the intestine in SARS patients. Furthermore, SARS-CoV causes lymphopenia which involves the depletion of T cells, probably by apoptotic mechanisms that are triggered by direct interactions of the SARS-CoV E protein with the antiapoptotic factor Bcl-xL. Also the MHV E protein has been reported to induce apoptosis. The SARS-CoV 7a protein was found to induce apoptosis in cell lines derived from lung, kidney, and liver, by a caspase-dependent pathway. Apoptosis has also been associated with arterivirus infection but information on underlying mechanisms and functional implications is limited.

Coronavirus and arterivirus infections trigger proinflammatory responses that often are associated with the clinical outcome of the infection. Thus, for example, there seems to be a direct link between the IL-8 plasma levels of SARS patients and disease severity, similar to what has been described for pulmonary infections caused by respiratory syncytial virus. In contrast, despite the upregulation of IL-8 in intestinal epithelial cells, biopsy specimens taken from the colon and terminal ileum of SARS patients failed to demonstrate any inflammatory infiltrates, which may be the consequence of a virus-induced suppression of specific cytokines and chemokines, including IL-18, in the intestinal environment.

Innate immunity is essential to control vertebrate nidovirus infection *in vivo*. The induction of type I IFN (IFN- α/β) varies among different coronaviruses and arteriviruses. Whereas some coronaviruses such as TGEV are potent inducers of type I IFN, other coronaviruses (MHV and SARS-CoV) or arteriviruses (PRRSV) do not stimulate its production, thus facilitating virus escape from innate immune defenses. Type I interferon is a key player in innate immunity and in the activation of effective adaptive immune responses. Upon viral invasion, IFN- α/β is synthesized and secreted. IFN- α/β molecules signal through the type I interferon receptor (IFNR), inducing the transcription of several antiviral mediators, including IFN- γ , PKR, and Mx. IFN- γ is critical in resolving coronavirus (MHV and SARS-CoV), and also arterivirus (EAV, LDV, and PRRSV) infections. Like many other viruses, coronaviruses have developed strategies to escape IFN responses. For example, it has been shown that the SARS-CoV 3b, 6, and N proteins antagonize interferon by different mechanisms, even though all these proteins inhibit the expression of IFN by interfering with the function of IRF-3.

In arteriviruses such as PRRSV, IFN- γ is produced soon after infection to promote Th1 responses. However, PRRSV infections or vaccination with attenuated-live PRRSV vaccines cause only limited IL-1, TNF- α , and IFN- α/β responses. This then leads to IFN- γ and Th1 levels that fail to elicit strong cellular immune responses.

Epstein–Barr Virus (*Herpesviridae*)

Lawrence S Young, University of Warwick, Coventry, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

Classification

Epstein-Barr virus (EBV) is a member of the genus *Lymphocryptovirus* (LCV) which belongs to the lymphtropic *Gammaherpesvirinae* subfamily of the family *Herpesviridae*. EBV is closely related to the LCVs present in hominids (e.g., chimpanzees) and other Old World non-human primates (e.g., baboons and macaques). These viruses share homologous sequences and genetic organization, and infect the B lymphocytes of their host species resulting in the establishment of persistent infection in vivo, B cell lymphomagenesis and the ability to immortalize B cells from their own natural host in vitro. LCVs have been isolated from common marmosets which are New World monkeys but these viruses show considerable divergence from the genomes of EBV and Old World primate LCVs suggesting that these viruses represent a more primitive predecessor of the LCVs infecting higher-order primates. LCV-specific genes can be classified into three groups based on evolutionary analysis: (1) universal herpesvirus genes common to all herpesviruses including genes important for virus replication and structure, (2) ancestral genes specific to the LCV genus responsible for intrinsic properties of these viruses such as B cell tropism, B cell transformation and virus reactivation, and (3) acquired LCV-specific genes that evolved later in the LCV genus and therefore are present in EBV and Old World LCVs but not New World LCVs, these include genes associated with the evasion of host immune responses.

Virion and Genome Structure

EBV is about 120–180 nm in diameter and has a similar structure to other herpesviruses with a core composed of linear dsDNA surrounded by a protein nucleocapsid comprising 162 capsomeres. There is a protein tegument which encompasses the nucleocapsid and is surrounded by a cell membrane-derived envelope containing both lipids and glycoprotein spikes which mediate virus infection (Fig. 1).

The EBV genome is composed of linear double-stranded DNA, approximately 172 kilobase pairs (kb) in length. EBV has a series of 0.5 kb terminal direct repeats (TRs) and internal repeat sequences (IRs) that divide the genome into short and long, largely unique sequence domains (Fig. 2). EBV was the first herpesvirus to have its genome completely cloned and sequenced. Since the EBV genome was sequenced from an EBV DNA *Bam*HI fragment cloned library, open reading frames (ORFs), genes and sites for transcription or RNA processing are frequently referenced to specific *Bam*HI fragments, from A to Z, in descending order of fragment size (Fig. 2). The virus has the coding potential for around 85 proteins, not all of which have been identified or characterized.

History

In 1958 Dennis Burkitt described a lymphoma that represented the most common tumor affecting children in certain parts of East Africa. The geographical distribution of this malignancy suggested that the development of this tumor, named Burkitt lymphoma (BL), might be due to an infectious agent possibly related to malaria. In 1964 the successful establishment of cell lines from explants of BL enabled Tony Epstein and Yvonne Barr to identify herpesvirus-type particles by electron microscopy within a subpopulation of tumor cells in vitro (Fig. 1). Werner and Gertrude Henle subsequently demonstrated that BL-derived cell lines expressed antigens that were recognized not only by sera from patients with BL but also by sera from patients with infectious mononucleosis (IM) and, at lower levels, from normal healthy individuals. Similar seroepidemiological studies also suggested a link between infection with this virus (now called Epstein-Barr virus after its discoverers) and undifferentiated nasopharyngeal carcinoma (NPC) leading to the subsequent direct demonstration of EBV DNA in the tumor cells of NPC. The ability of EBV to efficiently immortalize B lymphocytes in vitro and to induce tumors in non-human primates established this virus as a putative oncogenic agent in humans. Over the last 50 years EBV has been implicated in a variety of other lymphoid and epithelial malignancies.

Epidemiology and Natural History of Infection

EBV is the most common and persistent virus infection in humans with approximately 95% of the world's population sustaining a life-long asymptomatic infection. In underdeveloped countries, primary infection with EBV usually occurs during the first several months to few years of life and is predominantly asymptomatic. However, in developed populations, primary infection is more frequently delayed until adolescence or adulthood, in many cases producing the characteristic clinical features of infectious mononucleosis (IM) otherwise known as glandular fever.

EBV is orally transmitted and infectious virus can be detected in oropharyngeal secretions from IM patients, from immunosuppressed patients and at lower levels from healthy EBV seropositive individuals. The precise site of EBV replication in healthy individuals remains unknown but there is evidence that the virus replicates in differentiating epithelial cells in the oropharynx, in

Fig. 1 Electron micrograph of the Epstein-Barr virus virion.

salivary glands and in gingival cells. The nasopharynx and oropharynx are associated with a ringed arrangement of lymphoid tissue (so-called Waldeyer's ring) which may contribute to EBV shedding from virus-infected B cells being reactivated within the local mucosal environment and/or B cell-derived virus infecting and then replicating in differentiating epithelial cells.

EBV can be completely eradicated by irradiation in bone marrow transplant recipients suggesting that B lymphocytes are the main site of EBV persistence. This is supported by the B lymphotropism of EBV which is mediated by the binding of the major viral envelope glycoprotein gp350 to the CR2 receptor on the surface of B cells. Virion penetration of the B cell membrane requires further interactions between the EBV glycoprotein gp42 (which forms a ternary complex with gH and gL viral glycoproteins) and HLA class II molecules. It appears that the presence or absence of HLA class II in virus producing cells influences the tropism of EBV for B cells or epithelial cells by affecting the availability of gp42. Other CR2-independent pathways are responsible for EBV infection of epithelial cells, including secretory component-mediated IgA transport, integrin interactions with polarized epithelium and direct cell-to-cell contact, but these are relatively inefficient and of unknown relevance to EBV infection *in vivo*.

The B cell tropism of EBV and its ability to establish a latent infection in these cells both *in vitro* and *in vivo* further supports the contention that B lymphocytes are the reservoir of lifelong persistent infection. EBV can efficiently transform B cells *in vitro* converting approximately 3%–10% of all target B cells into permanently growing lymphoblastoid cell lines (LCLs) in which every cell carries multiple episomal copies of the EBV genome and expresses all latent genes (referred to as latency III or the "growth" program), including six Epstein-Barr nuclear antigens (EBNAs 1, 2, 3A, 3B and 3C) and EBNA leader protein (EBNA-LP), latent membrane proteins LMP1 and LMP2 (which encodes two isoforms, LMP2A and LMP2B) and the non-coding EBV-encoded RNAs (*EBER1* and *EBER2*) and viral microRNAs (miRNA) (Fig. 2). When peripheral blood lymphocytes from healthy EBV seropositives are placed in culture, the few EBV-infected B lymphocytes that are present regularly give rise to spontaneous outgrowth of EBV-transformed LCLs provided that immune T lymphocytes are either removed or inhibited by the addition of cyclosporin A to the culture. LCLs can also be generated by direct infection of resting B lymphocytes with EBV derived from the throat washings of seropositive individuals or from producer B cell lines. LCLs have provided an invaluable, albeit incomplete, model of the lymphomagenic potential of EBV.

Detailed examination of EBV infection *in vivo* has shown that the virus persists in the IgD⁺CD27⁺ memory B cell subset and that these cells have down-regulated the expression of most, if not all, viral genes. The precise route of entry of EBV-infected B cells into the memory compartment remains a subject of much debate. This reservoir of infected cells is stably maintained thereafter, apparently subject to the same physiologic controls as the general mucosa-associated memory B cell pool. EBV persistence within this B cell population brings with it the possibility of fortuitous antigen-driven recruitment of infected cells into germinal centers, leading to progeny that either re-enter the circulating memory pool or differentiate to plasma cells that may migrate to mucosal sites (Fig. 3). The different forms of latency that are manifest in virus-associated malignancies (discussed below) may represent latency programs that have evolved to accommodate such changes in host cell physiology (Figs. 3 and 4). Thus germinal center transit appears to activate a latency program where only the genome maintenance protein EBNA1 is expressed (latency 0), while exit from germinal centers is possibly linked to the transient expression of the EBV-encoded latent membrane proteins, LMP1 and LMP2 (latency II). The ability of these proteins to mimic the key signals required for B cells to undergo a germinal center reaction, namely T cell help via the CD40 pathway (constitutively provided by EBV-encoded LMP1) and activation of the cognate B cell receptor (augmented by EBV-encoded LMP2A), supports this strategy whereby EBV exploits the physiological process of B cell

Fig. 2 EBV and its latent genes. (a) Location and transcription of Epstein-Barr virus latent genes on the double-stranded viral DNA episome. The origin of plasmid replication (OriP) is shown in orange. The short green thick arrows represent exons encoding latent proteins: six nuclear antigens (EBNAs 1, 2, 3A, 3B and 3C, and EBNA-LP), latent membrane proteins (LMPs 1, 2A and 2B), BamHI fragment H rightward open reading frame (BHRF1) and BamHI-A fragment rightward reading frame (BARF1). The short blue arrows at the top represent the highly transcribed non-polyadenylated RNAs, *EBER1* and *EBER2*. The middle long green arrow represents EBV transcription during latency III, in which all the EBNAs are transcribed from either the Cp or Wp promoter; the different EBNAs are encoded by individual mRNAs that are generated by differential splicing of the same long primary transcript. The inner red arrow represents the EBNA1 transcript, which originates from the Qp promoter during latency I and latency II. Latency II is characterized by expression of EBNA1 together with the latent membrane proteins. Wp restricted latency is initiated from the Wp promoter and there is expression of all the EBNAs, except EBNA2, which is deleted in this form of latency (outer long blue arrow). (b) Location of open reading frames for EBV latent proteins on the BamHI restriction map of the prototype EBV B95-8 genome and including the viral microRNAs in sequence order. The BamHI fragments are named according to size, with A being the largest. Lowercase letters indicate the smallest fragments. TR refers to terminal repeats at each end of the genome. This region was often referred to as Nhet to indicate heterogeneity in this region according to the numbers of TRs within different virus isolates. BART, BamHI-A rightward transcript. Reproduced from Young, L.S., Yap, L.-F., Murray, P.G., 2016. Epstein-Barr virus: Over 50 years and still providing surprises. *Nature Reviews Cancer* 16, 789–802.

Fig. 3 Virus persistence in the B cells of the human host and the origin of EBV-associated B cell lymphomas. Upper panel: normal virus persistence. EBV resides in memory B cells of asymptomatic hosts. There are two models to explain how the virus enters memory B cells. In the germinal center model, EBV-infection of naïve B cells leads to a latency III ‘growth program’ in which the proliferation and expansion of the infected B cell pool is driven by expression of all EBV latent genes. Cells then enter the germinal center and express latency II (‘default program’), characterized by expression of EBNA1, LMP1 and LMP2. LMP1 provides a CD40-like signal and LMP2 a surrogate B cell receptor like signal; mimicking the same signals provided to the antigen-specific B cell in the normal germinal center. EBV-infected germinal center B cells leave the germinal center and enter the memory B cell pool. Here EBV protein expression is silenced (Latency 0); these cells are replenished by the same signals that normally induce the proliferation of memory B cells. Proliferating memory B cells require EBNA1 expression (Latency I) for viral episome segregation. Memory B cells can terminally differentiate into plasma cells (solid arrow) which triggers virus replication. EBV-infected germinal center B cells might also differentiate directly into plasma cells. (dashed arrow). In the ‘direct infection’ model (shown below), EBV accesses memory B cells following the direct infection of these cells which may involve a latency III intermediary. Lower panel: The origin of the EBV-associated B cell lymphomas. There is uncertainty about the exact stages of differentiation from which the EBV-positive B cell lymphomas arise (as indicated by the black dotted lines), as it cannot be assumed that the pattern of latency observed in the progenitor cell is recapitulated in the corresponding tumor. The figure illustrates the presumed (question marks indicate this uncertainty) cell of origin based on current evidence for post-transplant lymphoproliferative disease (PTLD), diffuse large B cell lymphoma (DLBCL), Hodgkin’s lymphoma and Burkitt’s lymphoma. Reproduced from Young, L.S., Yap, L.-F., Murray, P.G., 2016. Epstein-Barr virus: Over 50 years and still providing surprises. *Nature Reviews Cancer* 16, 789–802.

differentiation to access and maintain persistent infection in the memory B cell pool (Fig. 4). The possible commitment of these cells to plasmacytoid differentiation may trigger entry into lytic virus replication thereby providing a source of low-level virus shedding into the oropharynx. There may also be circumstances in which infected cells in the reservoir can reactivate back to proliferative infections similar to those of an EBV-transformed LCL.

EBV Strain Variation

The B cell-derived B95.8 strain of EBV was fully sequenced in 1984 and was, at that time, the largest DNA sequence (172 kb) ever determined. While variations in repeat regions of the EBV genome are observed amongst different EBV isolates, the genomes of viruses from different regions of the world or from patients with different virus-associated diseases are very similar. Strain variation over the EBNA2-encoding (BamHI WYH) region of the EBV genome permits all virus isolates to be classified as either “type 1” (EBV-1, B95.8-like) or “type 2” (EBV-2, Jijoye-like). This genomic variation results in the production of two antigenically distinct forms of the EBNA2 protein which share only 50% amino acid homology. Similar allelic polymorphisms (with 50%–80% sequence homology depending on the locus) related to the EBV type occur in a subset of latent genes, namely those encoding EBNA-LP, EBNA3A, EBNA3B and EBNA3C. These differences have functional consequences as EBV-2 isolates are less efficient in *in vitro* B lymphocyte transformation assays compared with EBV-1 isolates. A combination of virus isolation and sero-

Fig. 4 EBV-associated lymphomas display different patterns of virus latent gene expression. While the post-transplant lymphomas associated with EBV infection expression a pattern of latent gene expression similar to that observed in virus-transformed B cells *in vitro* (latency III), Hodgkin's lymphoma (latency II) and Burkitt's lymphoma (latency I) express more restricted forms of EBV latency. Upper panels show *in situ* hybridization for the abundant non-polyadenylated EBER transcripts which are expressed in all forms of EBV latent infection. The middle panels depict immunohistochemical staining for the EBNA2 protein which is only expressed in post-transplant lymphoma and not either Hodgkin's lymphoma or Burkitt's lymphoma. The bottom panels show immunohistochemical staining for the LMP1 protein which is expressed in post-transplant lymphoma and HL but not in BL.

epidemiological studies suggest that type 1 virus isolates are predominant (but not exclusively so) in many Western countries, whereas both types are widespread in equatorial Africa, New Guinea and certain other regions. The evolutionary relationship between the type 1 and type 2 strains of EBV remain obscure. They may have evolved from a common progenitor virus or through recombination of the ancestral LCVs infecting Old World primates. The pronounced (but not exclusive) segregation of EBV-2 isolates within equatorial regions suggests that environmental factors (including immunological competence) may have influenced EBV evolution and may still be responsible for the effective competition between EBV-2 isolates and the ubiquitous EBV-1 family.

In addition to this broad distinction between EBV types 1 and 2, there is also minor heterogeneity within each virus type. Individual strains have been identified on the basis of changes, compared with B95.8, ranging from single base mutations to extensive deletions. While infection with multiple strains of EBV was originally thought to be confined to immunologically compromised patients, more recent studies demonstrate that normal healthy seropositive individuals can be infected with multiple EBV isolates and that their relative abundance and presence may vary over time.

The possible contribution of EBV strain variation to virus-associated tumors such as BL and NPC which is common in China and South-East Asia, remains unknown. A number of studies have failed to establish an epidemiological association between EBV strain variation and disease concluding that the specific EBV gene polymorphisms detected in virus-associated tumors occur with similar frequencies in EBV isolates from healthy virus carriers from the same geographic region. However, these studies focussed on specific regions of the EBV genome rather than comparing the entire viral DNA sequence. More recent work using hybrid capture technologies and next generation sequencing (NGS) have facilitated routine sequencing from primary material and have confirmed that, while there is a high level of overall similarity of tumor-derived EBV strains with the prototypical EBV genome, variation exists in viral genes that might result in functional differences that influence tumor development. A recent case-control study of EBV strain variation in NPC has found distinct polymorphisms in the virus genome associated with the tumor thereby defining a high risk EBV variant that could be used to screen at risk populations and develop more precise diagnostic and prognostic tests.

Immune Response

EBV elicits both humoral and cell-mediated immune responses in infected hosts. Primary infection with EBV is associated with the rapid appearance of antibodies to replicative antigens such as VCA, EA and MA (gp350/220) with a later serological response to the EBNA proteins. In IM these responses are exaggerated and are accompanied by autoantibodies such as rheumatoid factor as well as a heterophile antibody response directed against antigens on the surface of sheep erythrocytes. These autoantibodies are the result of EBV-induced polyclonal B cell activation. In the chronic asymptomatic virus carrier, antibodies to VCA, MA and EBNA are found, the titers of which remain remarkably stable over time. Of these antibodies those against MA are particularly important

as they have virus neutralizing ability and can also mediate antibody-dependent cellular cytotoxicity. The levels of these EBV-specific antibodies are elevated in different EBV-associated diseases.

As with other persistent viruses, cell-mediated immunity plays an important role in controlling EBV infection. Primary EBV infection elicits a robust cellular immune response and the lymphocytosis observed in IM is a consequence of the hyperexpansion of cytotoxic CD8⁺ T cells with reactivities against both latent and lytic viral antigens. These reactivities are subsequently maintained at high level (up to 5% of the total circulating pool) in the CD8⁺ memory T cell pool. An EBV-specific CD4⁺ T cell response also contributes towards the control of EBV infection and, along with the CD8⁺ response, appears to be important in preventing the uncontrolled proliferation of EBV-infected B cells. Thus, impairment of the T cell response, either by immunosuppressive drug therapy or HIV infection, is responsible for the development of polyclonal lymphoproliferations that can progress to frank monoclonal non-Hodgkin's lymphomas (see below). These lesions can be controlled by adoptive therapy with EBV-specific T cells. The growth and survival of BL, NPC and Hodgkin's lymphoma (HL) in immunocompetent individuals implies that the tumor cells can evade EBV-specific T cell surveillance. This may be achieved by restricting EBV latent gene expression to those viral proteins not efficiently recognized by the T cell responses (i.e., away from expression of the highly immunogenic EBNA3 family), and/or by downregulation of target cell molecules required for immune recognition such as MHC class I/II and the antigen processing machinery which is mediated by the production of immunosuppressive EBV-encoded proteins such as those expressed during the EBV lytic cycle that inhibit antigen processing (e.g., BNLF2a), suppress macrophage function (vIL-10) and disrupt MHC class II presentation (e.g., BGLF5).

EBV-Associated Diseases

Infectious Mononucleosis

Primary infection with EBV in childhood is usually asymptomatic but when delayed until adolescence or early adulthood can manifest clinically as IM, a self-limiting lymphoproliferative disease characterized by a quartet of symptoms – sore throat, cervical lymphadenopathy, fever and fatigue. IM is associated with the massive expansion of activated CD8⁺ T cells that are reactive predominantly to EBV lytic cycle antigens with some limited responses against latent antigens. Immunodominant CD8⁺ T cell responses in IM are focussed on immediate early proteins (e.g., BZLF1 and BRLF1) and early proteins (e.g., BALF2, BMRF1, BORF2) and these reactivities are subsequently maintained in the CD8⁺ T cell memory pool at high levels. Activated CD4⁺ T cell responses specific for EBV epitopes in EBV lytic and latent antigens are also elevated in IM patients but fall rapidly as the disease resolves. IM appears to result in the global down-regulation of the alpha chain of the IL-15 receptor on T cells and NK cells, an effect which lasts for years after acute infection and may influence other disease risks. The incidence of IM is low in developing countries where asymptomatic primary infection predominantly occurs in childhood. In certain poorly defined situations IM-like symptoms can persist resulting in chronic active EBV infection (CAEBV) associated with elevated antibody titers to virus lytic antigens but low titers to the EBV-encoded nuclear antigens (EBNAs) along with elevated EBV infection in circulating T cells and NK cells. CAEBV appears to originate from an EBV-infected lymphoid progenitor and is associated with intragenic deletions in the EBV genome.

Multiple Sclerosis

Multiple Sclerosis (MS) is a chronic inflammatory demyelinating disease of the central nervous system (CNS), causing severe progressive disability. Genetic and environmental factors contribute to the development of MS and many studies implicate EBV including the universality of EBV infection in MS patients, elevated levels of antibodies against EBV in serum (particularly against the EBNA1 protein) during the course of MS and often years prior to the onset of the disease. Impairment of the EBV-specific CD8⁺ T-cell response, increased shedding of EBV from saliva and accumulation of EBV-infected B cells and plasma cells in the brain are also found in MS patients. It has been hypothesized that a defect in the CD8⁺ T cell control of EBV predisposes to MS by allowing EBV-infected autoreactive B cells and plasma cells to accumulate in the CNS. A recent phase I clinical trial using autologous EBV-specific T cell therapy demonstrated some clinical improvement in MS patients.

Lymphomas in Immunosuppressed Individuals

Patients with primary immunodeficiency diseases such as X-linked lymphoproliferative syndrome (XLP) and Wiscott-Aldrich syndrome are at increased risk of developing EBV-associated lymphomas. Because these tumors are extremely rare little is known about the precise contribution of EBV and the associated pattern of viral gene expression in these lymphomas. Mortality from XLP is high with around 50% of patients developing fatal IM after primary infection with EBV and an additional 30% of patients developing malignant lymphomas. The defect responsible for XLP is mutation of an adaptor molecule, SAP, which mediates signaling in a wide range of immune cells and is involved, via its interaction with the SLAM family of receptors, in both innate and adaptive immune reactions.

Allograft recipients receiving immunosuppressive therapy and patients with AIDS are also at increased risk for development of EBV-associated post-transplant lymphoproliferative disease (PTLD) and lymphomas. The incidence of non-Hodgkin's lymphoma (NHL) in AIDS patients, prior to the advent of highly active antiretroviral therapy, was increased approximately 60-fold compared

to the normal population. Around 60% of these tumors were large B cell lymphomas like those found in allograft recipients, 20% were primary brain lymphomas and 20% were of the Burkitt's lymphoma (BL) type. EBV infection was present in approximately 50% of AIDS-related NHL, nearly all the primary brain and Hodgkin's lymphomas, and in around 40% of the BL tumors. These NHLs range from polyclonal EBV-driven lymphoproliferations, much like that observed in vitro in virus-transformed LCLs (latency III, Figs. 2–4), to aggressive monoclonal non-Hodgkin's B cell lymphomas (NHLs) in which additional cellular genetic changes (e.g., mutation of p53) are present. The incidence of both PTLD and NHL B cell lymphomas in allograft recipients varies with the type of organ transplanted and with the type of immunosuppressive regimen used. PTLD in solid organ recipients are derived predominantly from recipient B cells whereas PTLD following hematopoietic stem cell transplantation are mainly of donor origin. Allogeneic bone marrow or solid organ transplantation into EBV seronegative children is a particular risk factor for the development of these lesions. A proportion of these lesions in post-transplant patients resolve in response to a reduction in immunosuppression or to targeted therapies such as anti-CD20 monoclonal antibody (rituximab) or adoptive EBV-specific T cells.

Diffuse Large B-Cell Lymphomas

EBV-positive diffuse large B-cell lymphomas (DLBCL) are monoclonal B-cell tumors that occur in patients over the age of 50 with no evidence of immunodeficiency or history of lymphoma. These lymphomas are thought to arise as a consequence of immunosenescence, present as two different morphologic variants (monomorphic and polymorphic) and are associated with extranodal involvement with the gastrointestinal tract, skin and bone marrow being the most commonly affected sites. EBV-positive DLBCL is more common in Asia than the West, representing around 8%–10% of DLBCL in Asian countries and 2%–5% of DLBCL in Western countries. The EBV-positive DLBCLs have a distinctive molecular profile with increased activity of certain cell signaling pathways (e.g., NF- κ B, STAT3, MAP kinase), probably as a consequence of EBV latent gene expression which is either of the latency II (EBNA1, LMP1, LMP2A) or latency III type. Intragenic deletions of various regions of the EBV genome have been found in a proportion of DLBCL.

EBV-positive DLBCL is an aggressive tumor with worse prognosis than the EBV-negative disease, particularly in Asian patients. EBV-positive DLBCL has also been found in younger patients but here the disease is very similar to EBV-negative DLBCL in terms of clinical outcome.

Burkitt's Lymphoma

The endemic form of BL which is found in areas of equatorial Africa and New Guinea represents the most common childhood cancer (peak age 7–9 years) in these regions with an incidence of up to 10 cases per 100,000 people per year. This high incidence of BL is associated with holoendemic malaria thus accounting for the climatic variation in tumor incidence first recognized by Dennis Burkitt. More than 95% of these endemic BL tumors (eBL) are EBV-positive compared with 20% of the low incidence, sporadic form of BL (sBL) which occurs worldwide. In areas of intermediate BL incidence, such as Algeria and Malaysia, the increased number of cases correlates with an increased proportion of EBV-positive tumors. Malaria is thought to contribute to endemic BL by inducing an intense polyclonal B cell activation, thereby increasing the target population for EBV infection, along with transient impairment of T cell immunity.

Seroepidemiological studies have demonstrated elevated antibody titers to EBV capsid antigen (VCA) and early antigens (EA) in BL patients compared to children without the tumor. These elevated antibody titers have been found to precede the development of BL and can therefore be used to screen "at risk" individuals. While sBL in high-income countries responds well to intensive chemotherapy, such regimens are not feasible or safe in low-income countries where late presentation is common and severe treatment-associated toxicities are difficult to manage. Recently modified protocols using cyclophosphamide and doxorubicin in eBL have resulted in much improved disease-free survival. Nevertheless, treatment failure is common and often associated with incomplete treatment, treatment-related mortality, relapse or progression of disease.

The pattern of EBV gene expression in BL is generally restricted to EBNA1 and the non-polyadenylated EBER transcripts (latency I) although broader virus gene expression involving the EBNA3 proteins and the viral Bcl-2 homolog BHRF1 has been observed in around 15% of tumors (Figs. 2–4). These so-called Wp-restricted BLs (named after the alternative virus Wp promoter that is used in these cells to drive EBV gene expression) carry an EBNA2-deleted EBV genome and, as a consequence of BHRF1 expression, are more resistant in vitro to apoptosis induced by cytotoxic drugs.

A consistent feature of BL tumors, irrespective of geographical location or EBV status, is chromosome translocations involving the long arm of chromosome 8 (8q24) in the region of the c-myc proto-oncogene and either chromosome 14 in the region of the immunoglobulin (Ig) heavy-chain gene or, less frequently, chromosomes 2 or 22 in the region of the Ig light-chain genes. BL tumors display a phenotype reminiscent of germinal center centroblasts with lower mutational frequencies in cancer driver genes such as *MYC*, *ID3*, *TCF3*, *CCND3* and *TP53* as compared to sBL. In contrast, a greater overall mutational load including higher frequency of mutations in *ARID1A* and loss of the regulatory role of PTEN have been found in eBL versus sBL. Some of these effects can be attributed to the influence of EBV-encoded genes in driving proliferation and survival in eBL without the need for mutations in other genes such as *TCF3* and *ID3*. Endemic BLs infected with EBV-2 appear to have a higher proportion of somatic mutations (similar to the levels observed in sBL) than those containing EBV-1. Thus, there are clear genetic and molecular distinctions between EBV-positive and EBV-negative BL that reinforce the crucial role of EBV in eBL pathogenesis.

Hodgkin's Lymphoma

Epidemiological studies originally suggested a possible role for EBV in the etiology of Hodgkin's lymphoma (HL). Thus, elevated antibody titers to EBV antigens have been detected in HL patients and these are present before the diagnosis of the disease. Furthermore, there is an increased risk of HL following IM. EBV has been demonstrated in around 40% of HL cases with both viral DNA, RNA and virus-encoded latent proteins (EBNA1, LMP1, LMP2 – latency II) localized to the malignant component of HL, the so-called Hodgkin's and Reed-Sternberg (HRS) cells (**Fig. 4**). These malignant cells are of germinal center origin but lack a functional B cell receptor, implicating EBV infection in the rescue of these so-called crippled cells from their usual apoptotic fate. Genetic mutations in components of various cell signaling pathways (e.g., NF- κ B, JAK/STAT, PI3K/Akt) are consistently found in EBV-negative HL as compared to the EBV-positive form of the disease. Thus, in EBV-positive HRS cells, the virus-encoded LMP1 oncoprotein is apparently sufficient to drive aberrant activation of these pathways in the absence of cellular mutations. Thus, EBV and cellular mutations probably provide mutually exclusive means to the same pathogenic end-point. The association of HL with EBV is age-related; pediatric and older adult cases are usually EBV-associated whereas HL in young adults is less frequently virus-positive. The proportion of EBV-positive HL in developing countries is high consistent with a greater incidence of HL in children and more frequent prevalence of the mixed cellularity histiotype; the histological subtype of HL in which EBV infection is most frequently detected. Although the incidence of HL is relatively low (1–3/100,000 per year), this tumor is not geographically restricted making its association with EBV significant in world health terms.

EBV-Associated T Cell and NK Cell Lymphomas

EBV-positive monoclonal lymphomas of either CD4+ or CD8+ T cell origin are more frequently found in Southeast Asian populations arising as a consequence of either virus-associated haemophagocytic syndrome (VAHS) or in the setting of CAEBV. There is also a distinct spectrum of EBV-positive T/NK lymphoproliferative disorders ranging from cutaneous lymphoid proliferations to aggressive extranodal T/NK lymphomas such as lethal midline granuloma, an erosive lesion of the nasal cavity. These lesions often develop in individuals with CAEBV, exhibit a latency II pattern of EBV latency with some evidence of early virus gene expression and frequently carry EBV genomes with intragenic deletions particularly over the BART miRNA region of the virus genome.

Nasopharyngeal Carcinoma

The association of EBV with undifferentiated NPC (WHO types II and III) was first suggested by serological evidence and then confirmed by the demonstration of EBV DNA in NPC biopsy material. NPC is particularly common in areas of China and South-East Asia, reaching a peak age-standardized incidence of around 25 cases per 100,000 per year. Incidence rates are particularly high in Cantonese males highlighting an important genetic predisposition as well as a role for environmental cofactors such as dietary components (e.g., salted fish). NPC tumors are characterized by a prominent stroma and the interaction between these stromal cells (activated lymphocytes, tumor-associated macrophages, cancer-associated fibroblasts etc.) and adjacent carcinoma cells appears to be crucial for the continued growth of the malignant component. EBV latent gene expression in NPC is restricted to EBNA1, the LMP2A/B proteins, the EBER, BARF1 and the BART miRNAs with a variable proportion of tumors also expressing the oncogenic LMP1 protein (latency II) (**Fig. 2**). While latent EBV infection appears to be a key driver in the development and progression of NPC, more detailed analysis of virus gene expression by RNA sequencing reveals a more complex pattern with expression of lytic genes associated with EBV replication. The precise levels and consistency of such EBV lytic gene expression in NPC remains unknown as does whether this has any impact on NPC pathogenesis.

Extensive serological screening for EBV-specific antibody titers in high incidence areas, in particular IgA antibodies to VCA and EA, have proved useful in diagnosis and in monitoring the effectiveness of therapy. The quantitative analysis of cell-free tumor-derived EBV DNA in the plasma of patients with NPC using real-time PCR (Q-PCR) is of both diagnostic and prognostic utility. A recent study has demonstrated that Q-PCR for plasma EBV DNA levels can also be used as a primary screening test, detecting early stage NPC which is more responsive to treatment.

The precise contribution of EBV infection to the development of NPC remains unclear. The presence of monoclonal EBV episomes in NPC tumor cells indicates that virus infection precedes the clonal expansion of the malignant cell population. However, the lack of epithelial EBV infection in normal nasopharyngeal biopsies from individuals at high risk of developing NPC suggests that epithelial infection may not be the initiating event in virus-associated carcinogenesis. EBV infection as detected by *in situ* hybridization to the EBER RNAs is found in high grade (severe dysplastic and carcinoma *in situ*) preinvasive lesions in the nasopharynx but not in low grade disease or histologically normal nasopharyngeal epithelium. Both the high grade and carcinoma *in situ* lesions carry monoclonal EBV genomes. A scheme has been proposed whereby loss of heterozygosity occurs early in the pathogenesis of NPC possibly as a result of exposure to environmental co-factors such as dietary components (i.e., salted fish) creating low grade preinvasive lesions that after additional genetic and epigenetic events become susceptible to EBV infection (**Fig. 5**). Once infected, EBV latent genes provide growth and survival benefits resulting in the development of NPC. Additional genetic and epigenetic changes occur after EBV infection and contribute to metastatic disease. Analysis of the genomic landscape in NPC has confirmed a role for chromatin modification in the carcinogenic process and identified additional somatic events including mutations in the ERBB-PI3K signaling pathway. A crucial role for the NF- κ B pathway in NPC pathogenesis has been recently identified and this appears to be either a consequence of LMP1 expression or of genomic aberrations in negative regulators of the NF- κ B signaling.

Fig. 5 Schematic representation of the pathogenesis of NPC. In nasopharyngeal carcinoma (NPC), the tumor cells carry monoclonal viral genomes indicating that EBV infection must have occurred prior to expansion of the malignant cell clone: EBV infection is detected in high-grade pre-invasive lesions in both NPC but not in low-grade disease. Multiple genetic changes have been found in NPC, with frequent chromosomal deletions and promoter hypermethylation of specific genes on chromosomes 3p, 9p and 11q. Deletions in both 3p and 9p have been identified in low-grade EBV-negative dysplastic lesions and in normal nasopharyngeal epithelium from individuals who are at high risk of developing NPC. *In vitro* studies demonstrate that CCND1 over-expression (a consequence of cyclin-dependent kinase inhibitor 2A [*CDKN2A* which encodes p16^{INK4A}] deletion on chromosome 9p and amplification of the *CCND1* locus on chromosome 11q) facilitates persistent EBV infection of immortalized nasopharyngeal epithelial cells. Increased expression of the anti-apoptotic protein BCL-2 and elevated telomerase activity in low grade dysplastic lesions may also promote the establishment of latent EBV infection. A scheme has been proposed whereby loss of heterozygosity (LOH) occurs early in the pathogenesis of NPC possibly as a result of exposure to environmental co-factors such as dietary components (i.e., salted fish) creating low grade preinvasive lesions that after additional genetic and epigenetic events become susceptible to stable EBV infection. Once infected, EBV latent genes provide growth and survival benefits resulting in the development of NPC. Additional genetic (e.g., LOH on chromosomes 11q, 13q, 14q and 16q) and epigenetic changes occur after EBV infection and contribute to metastatic disease. The precise timing of epigenetic events in the pathway of NPC development is unknown although some changes such as RASSF1A inactivation may occur early while others (e.g., inactivation of RARβ2, p14ARF and DAPK) may be influenced by the ability of EBV to enhance the activity of the methylation machinery. Recent analysis of the genomic landscape in NPC has confirmed a role for chromatin modification in the carcinogenic process and identified additional somatic events including mutations in the ERBB-PI3K signaling pathway. The pathogenesis of EBV-associated GC is similar to NPC with pre-malignant lesions occurring before EBV infection and a distinctive hypermethylation phenotype. CIS, carcinoma *in situ*; EDNRB, endothelin receptor B. Reproduced from Young, L.S., Yap, L.-F., Murray, P.G., 2016. Epstein-Barr virus: Over 50 years and still providing surprises. *Nature Reviews Cancer* 16, 789–802.

EBV infection is also associated with the more differentiated keratinizing form of NPC (WHO type I) particularly in those geographical regions with a high incidence of the type III tumor Carcinomas with similar features to undifferentiated NPC have been described at other sites (e.g., tonsils, uterine cervix) but, other than stomach tumors, these so-called undifferentiated carcinomas of nasopharyngeal type (UCNT) are not consistently EBV positive. EBV has been demonstrated in thymic epithelial tumors from Chinese but not Western patients. Salivary gland UCNTs are EBV-associated in Greenland Eskimos and Chinese but not in Caucasian patients.

Gastric Carcinoma and Other Epithelial Tumors

EBV infection is also present in around 10% of typical gastric adenocarcinomas, accounting for up to 90,000 cases per year worldwide. These EBV-GC tumors resemble NPC in carrying monoclonal EBV genomes, having a restricted pattern of EBV gene expression (EBERs, EBNA1, LMP2A, BARTs and BARF1) and in the appearance of virus infection as a relatively late event in the

carcinogenic process. EBV-GCs have distinct phenotypic and clinical characteristics compared to EBV-negative GC tumors including loss of p16 expression, p73 promoter methylation, wild type p53, a different pattern of allelic loss and improved patient survival. Comprehensive genomic and molecular characterization of GC tumors has confirmed that EBV-GCs are a distinctive entity with a high CpG island methylator (CIMP) phenotype and apparent driver mutations in the PIK3CA and ARID1A genes.

Control and Prevention of EBV Infection

While a number of nucleoside (e.g., acyclovir, ganciclovir, famciclovir) and nucleotide (e.g., cidofovir, foscavir) analogs are approved for the treatment of herpes simplex virus (HSV-1 and HSV-2), varicella-zoster virus and human cytomegalovirus, none are used routinely in the treatment of acute EBV infection. This may reflect difficulties in diagnosing IM, its long incubation period and, more significantly, the immunopathology of IM which results in symptoms that are related to the immune response to EBV-infected B lymphocytes rather than virus replication. Nevertheless, antivirals such as acyclovir and ganciclovir have been used in patients with CAEBV and in immunosuppressed patients where such prophylaxis reduces the incidence of PTLT.

The conventional approaches of chemotherapy and radiotherapy are used to treat primary EBV-associated tumors. It is only in the context of relapsed, refractory or metastatic cancer that novel therapeutic strategies specifically targeting EBV proteins or exploiting the presence of the virus in malignant cells are being developed. Demethylating agents such as 5'-azacytidine or histone deacetylase (HDAC) inhibitors such as SAHA are able to induce the EBV lytic cycle including virus-encoded kinases (EBV thymidine kinase and BGLF4, a protein kinase) that can phosphorylate the nucleoside analog ganciclovir to produce its active cytotoxic form. These agents, which are continuing to be assessed in clinical trials, also induce expression of the more immunogenic EBV latent genes in NPC and HL as well as creating a tumor immune microenvironment that supports enhanced anti-tumor immune responses. Other experimental approaches are based on targeting individual EBV latent proteins either indirectly by inhibiting signaling pathways activated, for instance, by LMP1 (e.g., NF- κ B, PI3-kinase) or more directly using specific inhibitors such as siRNA or dominant negative molecules. More recently specific inhibitors of the EBNA1 protein have been developed and these are showing therapeutic promise in pre-clinical models.

The use of adoptive EBV-specific T cell therapy for the treatment of existing PTLT and in the prophylactic setting has been extremely successful. This approach is also showing signs of some clinical efficacy in NPC when T cells are enriched for reactivities to subdominant targets (e.g., LMP2A and EBNA1). More direct vaccine approaches to treat patients with EBV-associated tumors or to prevent disease development are being examined including: (1) whole EBV latent antigens delivered by a virus vector or in autologous dendritic cells; (2) peptide or polytope vaccination and (3) prophylactic vaccination against MA (gp350/220) on the virion surface or virus-like particles to generate a neutralizing antibody response.

Future Perspectives

EBV was discovered over 50 years ago and its DNA was fully sequenced in 1984. It remains the most common persistent virus infection in humans – testimony to the intimate interaction between EBV and the immune host. This relationship relies on the ability of EBV to persist in the memory B cell pool of normal healthy individuals and corruption of this process leads to the development of virus-associated lymphomas. The role of EBV infection in NPC is less clear and may be a consequence of the aberrant establishment of *virus* latency in epithelial cells that have already undergone pre-malignant genetic changes.

The development of more efficient *in vitro* systems for studying EBV infection and replication in different cell types along with the use of recombinant forms of EBV is shedding light on the complex interplay between the virus and host. Improvements in virus genome sequencing technologies as well as the ability to clone wild-type EBV strains for biological characterization will facilitate a better understanding of the natural history of EBV infection and how the virus contributes to the oncogenic process. These systems, along with detailed analysis of EBV-associated tumors, are already providing insights into the interaction of the virus with the tumor microenvironment and how this influences the local cytokine milieu to promote tumor growth and immune evasion. There are many interesting aspects of EBV biology that remain to be understood including the role of virus-encoded microRNAs and the possible contribution of lytic cycle antigens to virus persistence and oncogenesis. The challenge will be to exploit these new mechanistic insights both to gain a better understanding of EBV infection *in vivo* and to develop novel therapies for treating virus-associated disease.

Equine Herpesviruses (*Herpesviridae*)

Gisela Soboll Hussey, Michigan State University, East Lansing, MI, United States

Introduction

The first disease attributed to a herpesvirus of horses, the agent that is now referred to as equid herpesvirus type 1 (EHV-1; equine abortion virus), was documented at the University of Kentucky Agricultural Experiment Station in Lexington, KY. EHV-1 was first shown to be associated with spontaneous abortions in pregnant mares in 1932. In 1941 and 1949, equine abortions and/or paresis were found to be associated with mild respiratory disease with clinical signs similar to those associated with equine influenza virus infections. EHV-1 was also shown to be the etiological agent of epizootic respiratory disease in young horses. Based on these investigations, the disease was termed viral rhinopneumonitis, and the agent was called equine rhinopneumonitis virus. In the 1980s, however, the two disease manifestations, viral abortion and viral rhinopneumonitis, were shown to be caused by two closely related but clearly distinct viruses that are now classified as EHV-1 (equine abortion virus) and EHV-4 (equine rhinopneumonitis virus). EHV-1 is the cause of respiratory disease in young animals, as well as equine abortions, highly fatal neurological disease, fulminating neonatal pneumonitis, ocular chorioretinal lesions and very rarely, an exanthematous condition involving the external genitalia of the mare.

Equid herpesvirus type 2 (EHV-2) was first isolated from horses in 1963. The cytopathology caused by this virus closely resembled that of cytomegalovirus infections which were first described in 1921 in humans. EHV-2 is a ubiquitous slow-growing virus that infects horses at a very young age (1–2 years) and establishes a life-long chronic infection such that the virus is continually shed. To date, no major disease has been attributed to EHV-2. An association of EHV-2 with chronic throat infections (the lumpy bumpies) or recurrent eye disease (keratoconjunctivitis) has been established; however, causal relationships have not been unequivocally proven. In addition, EHV-2 may be a cofactor in EHV-1 and/or EHV-4 infections in that it may be able to modulate EHV-1 and EHV-4 replication by an immunosuppression causing general malaise or by modulation of EHV-1 gene expression through EHV-2-specific transcriptional transactivators.

Equid herpesvirus type 3 (EHV-3; equine coital exanthema virus, ECE virus) was first isolated in 1968, concurrently in Canada, Australia and the US. EHV-3 is the etiological agent of equine coital exanthema, a generally mild genital infection of both mares and stallions that is transmitted venereally. Clinical signs include the formation of papules, vesicles, pustules, and ulcers on genital organs. Although mild, EHV-3 infection has negative impact on equine breeding and can cause temporary disruption of the mating season, artificial insemination, and embryo transfer. Sporadic cases of EHV-3 infection with periodic virus shedding and virus isolation are still reported.

Equid herpesvirus type 4 (EHV-4; equine rhinopneumonitis virus), is associated mainly with respiratory disease, but has also been associated occasionally with equine abortions. EHV-4 is most commonly detected in weaned foals and yearlings. Adult horses are also susceptible to EHV-4 infection, however, they show milder clinical signs or infections remain subclinical.

Equid herpesvirus type 5 (EHV-5) is closely related to EHV-2 and is frequently detected in (healthy) horse populations worldwide. In 1970, EHV-5 was first isolated from the nasal cavity of two horses in quarantine in Australia. It has been thought that the virus is harmless and cause no clinical disease but there is mounting evidence that EHV-5 is associated with equine multinodular pulmonary fibrosis (EMPF). More definite proof for direct causation of EHV-5 and EMPF and a clearer understanding of the pathogenesis is needed, however, before a solid conclusion can be reached.

Equid herpesvirus type 9 (EHV-9), previously referred to as gazelle herpesvirus 1, was first isolated from a captive Thomson's gazelle suffering neurological signs in 1993 in Japan. It has been shown to be closely related, but clearly distinct, from EHV-1. The natural host and the true host range of EHV-9 is still unknown but the virus has a relatively wide host range and infects equid and non-equid species in the wild and in captivity. EHV-9 was used for experimental infection of a number of animal species, including dogs, cats, mice, cattle, hamsters, goats, pigs, macaques and marmosets, in all of which it causes a highly lethal neurological disorders.

Classification

EHV-1, EHV-2, EHV-3, EHV-4, EHV-5, and EHV-9 are all members of the *Herpesviridae* but belong to two different subfamilies (*Alpha-* and *Gammaherpesvirinae*) in this large virus family. EHV-6, 7 and 8 are also referred to as asinine herpesviruses 1, 2, and 3, respectively (AsHV-1 to AsHV-3), and will not be discussed in this article. The morphology of all six members is typical of the herpesviruses in that they are enveloped, contain an icosahedral capsid, and have a proteinaceous layer, the so-called tegument, which surrounds the nucleocapsid. Equine herpesviruses are composed of six distinct species: (1) EHV-1 is the major equine pathogen causing abortions, respiratory illness, neurological disease and ocular disease; (2) EHV-2 establishes asymptomatic long-term persistent infection and might be associated with keratoconjunctivitis; (3) EHV-3 is the causative agent of mild pro genital

Table 1 The equine herpesviruses

<i>Properties of the viral genome</i>				
<i>Member</i>	<i>Subfamily</i>	<i>Isomers</i>	<i>G + C ratio (%)</i>	<i>Clinical manifestations</i>
EHV-1	<i>α-herpesvirinae</i>	2	57	abortion, respiratory infection, paralysis
EHV-2	<i>γ-herpesvirinae</i>	1	58	chronic throat infection; keratoconjunctivitis
EHV-3	<i>α-herpesvirinae</i>	2	68.1	equine coital exanthema
EHV-4	<i>α-herpesvirinae</i>	2	50.5	respiratory infections
EHV-5	<i>γ-herpesvirinae</i>	1	55	equine multinodular pulmonary fibrosis
EHV-9	<i>α-herpesvirinae</i>	2	56	encephalitis in non-definitive hosts

exanthema; (4) EHV-4 is a major respiratory pathogen that differs significantly from EHV-1 at the DNA level, and is associated occasionally with equine abortions; (5) EHV-5 may be associated with equine multinodular pulmonary fibrosis; (6) EHV-9 can cause subclinical encephalitis in horses under experimental conditions. Experimental and accidental natural infections of non-equid species are mostly lethal due to severe neurological disorders. In this latter respect, EHV-9 possesses biological properties very akin to the alphaherpesvirus of pigs, pseudorabies virus.

EHV-1, 3, 4, and 9 are *Alphaherpesvirinae* members and belong to the genus *Varicellovirus*. EHV-2 and EHV-5 are members of the *Gammaherpesvirinae* and are classified into the genus *Percavirus*.

Virion Structure

Infectious EHV-1 and EHV-4 particles contain an envelope that is mainly composed of glycoproteins. To date, twelve glycoproteins have been identified and an association of gB, gC, gD, gE, gH, gL, gM, gp2, gI, gK, ORF10 (UL49.5) with purified virions has been demonstrated. The glycoproteins were shown in other alphaherpesviruses to be involved in virus attachment and binding, penetration, egress and cell-to-cell spread of infection as well as immune evasion. Less is known for proteins that make up the third component of the mature virion, the tegument. In all cases, EHV-1 and EHV-4 encode homologs to most of the HSV-1 tegument proteins that have been surmised to exert the same function.

Three different EHV-1 capsid species were identified and probably correspond to the capsid forms found in HSV-1, which are designated type A, B, and C capsids. The EHV-1 capsid species were designated: (1) L capsids, which appear to be empty capsids; (2) I capsids, which possess an electron lucent, immature core structure in the shape of a cross; and (3) H capsids, which contain an electron dense, mature core. All three capsids appear at approximately 6 h postinfection. I capsids are believed to be a major precursor in the formation of mature capsids. The major capsid protein has an apparent size of 148 kD, while other structural proteins have also been identified.

Genomes

All six equine herpesviruses contain a linear, double-stranded DNA genome ranging between 140 and 184 kbp. The reported approximate molecular masses of the genomes are: EHV-1 (Ab4 strain), 150 kbp; EHV-2, 184 kbp; EHV-3, 152 kbp; EHV-4, 145 kbp; EHV-5, 182 kbp; and EHV-9, 148 kbp. The genomes of EHV-1, EHV-3, EHV-4, and EHV-9, exist in two isomeric forms, since the short region (S) can invert relative to the fixed orientation of the unique long region (UL). The S region is comprised of a central segment of unique sequences (US) bracketed by a pair of inverted sequences (IR). In contrast, the genomes of EHV-2 and EHV-5 exist as one isomer and are comprised of a large central segment of unique sequences that is bracketed by a pair of direct repeat sequences. The EHV-2 genome contains direct terminal repeats (TR) of 17,553 and 18,332 bp, respectively. While the TR of EHV-5 is much smaller (10 bp) in each terminal. Other characteristics of the genomes of EHV-1 and EHV-9 are shown in [Table 1](#) and [Fig. 1](#).

There are varying degrees of homology at the DNA level among the six equine herpesviruses. The sequences shared by the EHV-1, EHV-3, EHV-4, and EHV-9 appear to be arranged colinearly. EHV-1 and EHV-9 exhibit the highest degree of nucleotide identity, ranging from 86% to 95%. EHV-1 and EHV-4 have 55%–84% sequence identity at the DNA level. EHV-1, EHV-4, and EHV-9 are antigenically very closely related and antibodies can cross-react. EHV-3 is the most divergent among the equid alphaherpesviruses and only shares an overall identity of approximately 60% with EHV-1, EHV-4 and EHV-9 ([Fig. 2](#)). EHV-2 and EHV-5 show approximately 62% identity on the DNA level.

The EHV-1 and EHV-4 genomes have been cloned as bacterial artificial chromosomes (BAC). These infectious clones provide a basis for rapid and efficient mutagenesis in prokaryotic cells. A variety of recombinant viruses that lack non-essential genes or portions of an essential gene or with swapped genes have been generated and used in experiments to elucidate the functions of these genes in virus replication and/or pathogenesis.

The complete EHV-1 (Ab4 strain) genome is 150,223 base pairs in size, while that of EHV-4 is 145,597. The EHV-1 genome has at least 78 unique corresponding genes [63 ORFs in the UL region, 6 ORFs in each inverted repeat (IR and TR), and 9 ORFs in the US segment]; however, the actual number of open reading frames (ORFs) in the genome is 84 due to duplication of the six genes

Fig. 1 Schematic presentation of the genomic organization of equine herpesvirus genomes.

Fig. 2 Phylogeny of equid herpesviruses. Genetic relationships of four equid *Alphaherpesviruses* and two equid *Gammapherpesviruses* are shown.

in the inverted repeat, and, based on recent discoveries in other herpesviruses, this number likely is a large underestimation. The EHV-4 genome harbors at least 76 unique genes and 79 ORFs due to duplication of three genes of the inverted repeats. The 63 open reading frames of the UL region are arranged colinearly between EHV-1 and EHV-4 and with those in the genomes of herpes simplex virus and varicella zoster virus. Several genes mapping within IR and US region differ in arrangement from those of other alphaherpesviruses. In addition, EHV-1 and EHV-4 contain a limited number of unique genes that are present neither in HSV-1 nor in VZV which might represent the viruses' gene repertoire determining host specificity.

A comparative genome sequencing study of three EHV-1 strains (Ab4: neuropathogenic strain; RacL11: abortogenic strain; KyA: non-pathogenic strain after serial passages in mouse fibroblast 1-M cells) revealed that KyA genome is the shortest with 141,350 bp when compared to the RacL11 genome, 147,469 bp, and the Ab4 genome, 150,223 bp. Sequence analysis showed that ORF1 and ORF2 genes are deleted in both KyA and RacL11 strains, while other deletions of ORFs 17, 73, 74, and 75 were only detected in the KyA strain. Identical in-frame deletions in ORFs 14, 63, and 68 were observed in both RacL11 and KyA, while extra in-frame deletions in ORFs 61 and 71 were observed only in KyA strain. On the other hand, EHV-4 viruses appeared to be more conserved with minimal changes in their genomes, even when analyzing the genomes of EHV-4 that was suspected to be the cause of abortion in mares.

Six genes and the origin (ORI) of replication have been mapped to the IR sequences of EHV-1, while the remainder of the genes locates in the unique regions of the genomes. Unique genes (ORFs 2, 3, 34, 58, 67, 75, and IR2 and IR3) of EHV-1 and some of EHV-4 with no homologs in HSV-1 have been identified and mapped to the UL, US, and repeat regions. In addition, another interesting gene (ORF71, gp2) was mapped in the US segment. This gene encodes a highly O-glycosylated protein referred to as gp2. Some size variations of gp2 were documented for EHV-1 strains KyA and wild-type strains Ab4 or RacL11. A gp2-null mutant was apathogenic in a murine model of EHV-1 infection. Replacement of the truncated gp2 gene of the apathogenic KyA virus with the gp2 gene of the pathogenic RacL11, which encodes for the full-size gp2 of 791 amino acids, resulted in a "transfer" of pathogenic properties, such that full-length gp2 is a major determinant of virulence.

The EHV-9 genome is shorter, 148,371 bp, than the genome of EHV-1 (Ab4 neuropathogenic strain). The genome has in total 80 open reading frames that also present in EHV-1; however, no information about the presence of IR2 or IR3 is available. The

Table 2 Regulatory genes of EHV-1

Gene	Temporal class	Gene product	Function in replication
IE	Immediate early	1,487aa	Trans-activates early genes and activates some late genes
IR4	Early	293aa	Enhances IE protein DNA binding and binds TBP
UL5	Early	470aa	Binds the IE protein, TFIIB, and TBP
EICP0	Early		Promiscuous trans-activator, which Antagonizes IE protein function; binds IE protein, TFIIB, TBP
IR2	Early	1,165aa	Dominant negative regulator, which blocks IE protein binding to promoters
IR3	Early	0.9kb RNA	Antisense to IE mRNA; precursor to microRNA?
ETIF	Late	479aa	Trans-activates the IE promoter; essential for virus egress

EHV-9 genome has a high degree of similarity with EHV-1, with ORFs 42, 52, and 53 showed the highest degrees of identity (95%) and ORF71 the lowest (86%). One frameshift in ORF68 was detected when compared to EHV-1.

The genomic sequences of EHV-2, EHV-3, and EHV-5 have now been determined, but intensive research on gene functions has not yet been performed.

Life Cycle

The initial attachment of EHV-1 and EHV-4 virions to cells occurs through the interaction of gC with cellular heparan sulfate, while gD is essential for virus entry after binding to specific cellular receptors. EHV-1 gD was shown to utilize unique and wide range of entry receptors that enables the virus to enter and infect cell types of different origins. Equine major histocompatibility (MHC) class I molecules were determined as the gD-binding receptors for both EHV-1 and EHV-4. Yet, these two viruses can still infect other non-equine cells independently of equine MHC-I. The interaction between EHV-1 gH and cellular $\alpha 4\beta 1$ -integrins have been shown to induce release of Ca^{2+} from intracellular stores and facilitate fusion of the viral envelope with the plasma membrane.

Transcription and translation of EHV-1 genes have been studied best for the KyA strain. The genes of the KyA virus are regulated at the transcriptional and translational levels in a temporal fashion, and three kinetic classes of genes designated immediate-early (IE), early (E) and late (L) have been described. The sole IE gene (IR1) maps in both IR segments and gives rise to a spliced 6.0 kbp mRNA. Multiple IE polypeptide species have been observed, and the major IE protein (IE1, 203 kD) is a nuclear-localized phosphoprotein that is capable of *trans*-activating other viral genes and auto-regulating its own transcription. Previous studies revealed that the IE protein harbors domains for binding general transcription factors, such as TFIIB and TATA-binding protein (TBP), and thus serves to promote the formation of pre-initiation complexes that mediate viral transcription. Following IE polypeptide synthesis, approximately 45 early transcripts can be detected. Four of these early proteins serve as regulatory proteins and are designated IR4 (EICP22), UL5 (EICP27), EICP0 (UL63) and IR2 (Table 2). The IR4 protein physically interacts with the IE protein and serves to enhance the DNA-binding of the IE protein to its target sequence (ATCGT) present within the promoters of EHV-1 genes characterized to date. IR4p also binds to TBP and is present at early viral promoters in association with the IE protein and TBP. These interactions explain the synergistic effect on the *trans*-activation of viral genes mediated by the IE and IR4 proteins. The EHV-1 homolog of ICP27 of HSV-1 is essential for virus replication in cell culture. It acts synergistically with either the IE protein or the EICP0 early regulatory protein to activate expression of both early and late viral gene expression. The third early regulatory protein is EICP0p, which is a powerful and promiscuous *trans*-activator that can independently activate expression of viral genes of all three temporal classes. Deletion of the *EICP0* gene greatly impairs virus replication and severely retards late gene expression, suggesting that this regulatory protein is important in the switch from the early to late phase of viral gene programming. The fourth early regulatory protein is the IR2 protein that is a truncated form of the IE protein that lacks its essential *trans*-activation and serine-rich domains. The IR2 protein serves a negative regulatory role as it down-regulates viral gene expression by acting as a dominant negative protein that blocks IE protein binding to viral promoters and/or by squelching the limited supply of TFIIB and TBP. In addition to these four early auxiliary regulatory proteins, the EHV-1 unique IR3 gene contributes a regulatory role as it encodes a small transcript that is antisense to a portion of the IE transcript. In transient transfection assays, the IR3 transcript down-regulates IE gene expression and is only minimally expressed to a protein. Initial studies suggest that the IR3 transcript is processed to a microRNA, and thus the IR3 gene may use novel mechanisms to down-regulate IE gene expression at late times of infection. Early gene expression is followed by viral DNA replication and the production of approximately 29 late transcripts. Although these 75 transcripts have been positioned on the viral genome, only a small number of protein products have been identified and characterized (see above).

Viral DNA replication initiates at approximately 4 h postinfection and requires the virus-encoded DNA polymerase. DNA replication is thought to occur by the rolling circle mechanism whereby long concatemers of the viral genome are generated, cleaved and then packaged into the maturing virions. The UL15 homolog of HSV-1, one of the two spliced genes of EHV-1 known to date, appears to be essentially involved in the generation of unit-length genomes and their packaging into mature capsids.

The start of viral DNA synthesis initiates the late phase of viral gene expression and the synthesis of the late regulatory protein ETIF, a counterpart to the *alpha trans* inducing factor of HSV-1. This 60 kDa protein is multifunctional and plays at least three roles in EHV-1 replication. ETIF in several molecular sizes is present in the tegument and thus contributes to the composition of this

virion component and overall virion structure. Secondly, after virus entry and uncoating, ETIF serves to *trans*-activate the *IE* promoter by binding to cellular factors that mediate its association with the TAATGARATT sequence at nt -630 to -620 in the *IE* promoter. This *trans*-activation function to initiate viral gene programming is important but is not essential as EHV-1 DNA is infectious and virus progeny are produced in cells transfected with plasmids carrying the EHV-1 genome. The activation of a viral promoter by ETIF is specific for the *IE* promoter as ETIF is not able to *trans*-activate any early or late promoter tested to date. ETIF-deleted virus (Δ ETIF) and an ETIF complementing cell line revealed that ETIF plays a key role in secondary envelopment. As reported for other herpesviruses, EHV-1 maturation occurs by interaction of mature nucleocapsids with the inner portion of the nuclear membrane resulting in the formation of enveloped particles. Studies with Δ ETIF and Δ US3 EHV-1 support the model of the sequential envelopment/de-envelopment/re-envelopment for the egress of EHV-1. Nuclear egressed-nucleocapsids are transported to the TGN, where additional tegument proteins are recruited and the envelope with glycoproteins is acquired. The mature virions are released extracellularly through exocytosis.

Latency

Like other members of the *Alphaherpesvirinae*, equid herpesviruses establish latency in different cell types in the horse after primary infection. Under stress or following immunosuppression, periodic reactivation from latency usually happens and leads to viral shedding and horizontal transmission. EHV-1 has been shown to establish latent state in leukocytes, lymphoid tissues, and neuronal cells of the trigeminal ganglion. EHV-4 can establish latency in trigeminal ganglia and lymphoid tissues. EHV-2 is thought to establish latency in B-lymphocytes, macrophages, lymphoid tissues, peripheral and central nervous systems, and possibly Langerhans cells. Potential sites of EHV-3 and EHV-5 latency are not yet identified; however, mononuclear cells are surmised to be the major site of EHV-5 latency. The location of EHV-3 latency is presumed to be the sciatic or sacral ganglia. Interestingly, latent state of EHV-1 and EHV-9 in the sensory ganglia of zebras has been identified.

Epidemiology

In general, herpesviruses are species-specific and it has long been thought that these viruses have co-evolved with their hosts over millions of years; that is how equine herpesviruses acquired their nomenclature. Advances in sequencing technology and screening a wide range of species might now take the lead to change this general concept (i.e., herpesviruses are strictly species-specific) as there is clear evidence of frequent virus transfer beyond the definitive host.

The horse is the natural host of EHV-1, -2, -3, -4, and -5, while the definitive host of EHV-9 is still unknown. Wild equids (zebras and onagers) and domestic donkeys can also serve as a host of EHV-1. Further, EHV-1 has a broad host range and the virus can infect several non-equid species including captive gazelles, antelopes, cattle, alpacas, llamas, black bears, polar bears, black and Indian rhinoceros, and Indian tapir. EHV-9 infections have been also documented in non-equid species, such as gazelles, giraffes and polar bears. A recombinant virus of EHV-1 and EHV-9 was detected in lung and brain tissues of an Indian rhinoceros and polar bears. Serological studies indicated the presence of EHV-1 antibodies in African white and black rhinoceroses, while EHV-9 antibodies were widespread high-titered in zebras and even more so in white and black rhinoceroses. It is generally thought, however, that both EHV-1 and EHV-9 will not replicate to high levels in most non-definitive hosts and that no interindividual spread occurs.

Epidemiological studies concerned with determining the host range of other equid herpesviruses are limited. The currently available reports show that the host range of EHV-2, EHV-3, EHV-4, and EHV-5 is more restricted than that of EHV-1. Domestic donkeys have been shown to be infected with EHV-2, EHV-4, and EHV-5.

In addition to equine influenza virus, EHV-1 and 4 are considered to be the most relevant clinical equine viral respiratory pathogens. However, of the equine herpesviruses, subclinical detection of virus in respiratory secretion or blood samples is most common for EHV-5 and EHV-2 followed by EHV-4 and then EHV-1. For all of the equine herpesviruses the main epidemiologically relevant features include: (1) High incidence of respiratory infection early in life; (2) Establishment of latency in a high percentage of infected horses; (3) Frequent reactivation of latent virus with subsequent shedding, resulting in transmission to naïve hosts. Currently, it is estimated that as many as 80% of all horses are latently infected with EHV-1 and seroprevalence for EHV-4 is typically even higher. Prevalence may vary depending on geographic region, age and population. Furthermore, testing technology and tissues sampled for detection of latency affect sensitivity of testing and actual numbers of latently infected horses may be even higher.

Rhinopneumonitis caused by EHV-1 and EHV-4 is spread by direct or indirect contact (ingestion and inhalation). The viruses are shed in nasal droplets for up to three weeks and are present in large amounts in aborted fetuses and the placenta. EHV-1 infection can also result in spontaneous abortions in pregnant mares between the eighth and eleventh months of pregnancy. The peak incidence is in the ninth and tenth months at which time approximately 70% of abortions occur. Presence of EHV-1 and histological lesions following infection with EHV-1 have also been reported in testis and semen of infected stallions but a venereal transmission has not been reported. Duration of shedding following recrudescence varies, but because prolonged shedding has been detected particularly in cases of equine herpesvirus myeloencephalopathy (EHM) outbreaks, current recommendations are to wait 28 days before lifting quarantine measures.

EHV-2 and EHV-5 are endemic worldwide with high seroprevalence, and co-infections are common. The viruses have been isolated from the respiratory tract, conjunctiva, blood leukocytes, kidneys, spleen, testicles, genital tract and rectum, however

isolation is primarily reported from the respiratory tract, the conjunctiva and blood cells, which are presumed sites of primary infection and latency. Once infected, the horse is a life-long carrier and excreter of the virus. The exact mode of spread for EHV-2 and EHV-5 is unknown but horizontal transmission is the likely mode of transmission under field conditions.

EHV-3 causes a mild coital exanthema that is spread by genital contact and – rarely – the respiratory route or via contact with contaminated objects. Information on seroprevalence is similarly limited and reported rates range from 6% to 48%. EHV-3 infection is usually cleared after 14 days and is not associated with equine abortions.

Pathogenesis and Immune Response

Although EHV-1 and EHV-4 respiratory infections are clinically indistinguishable, their pathogenesis is quite different. Primary infection with EHV-1 and EHV-4 occurs via the respiratory tract by inhalation of infectious virus, nose-to-nose contact, or contact with contaminated tissues or fomites. Following infection and replication in the respiratory airway epithelium, EHV-1 can be detected by 24–48 h in the local lymph nodes of the respiratory tract and a cell-associated viremia is established between days 4 and 10 post infection. In contrast, a cell-associated viremia is not commonly observed with EHV-4, which stays restricted to the respiratory tract. For EHV-1, the cell-associated viremia transports the virus to sites of secondary infection where contact between infected leukocytes and the vascular endothelium leads to endothelial cell infection, inflammation, thrombosis and tissue necrosis and secondary disease manifestations directly following viremia. Secondary disease manifestations for EHV-1 include equine herpesvirus myeloencephalopathy (EHM), EHV-1 abortions, neonatal foal death and chorioretinopathies. Because a cell associated viremia is the pre-requisite for transport of the virus to sites of secondary infection, including EHM and late term abortions, EHV-4 is only occasionally associated with abortion and extremely rarely with neurological disorders. While a positive correlation between the duration and magnitude of viremia and incidence of EHM has been identified, and EHM is unlikely to occur in the absence of viremia, only a small percentage (~10%) of viremic horses subsequently develop EHM. A combination of host and viral factors have at this point be identified to be associated with incidence of EHM including age, breed, gender, season as well as a single nucleotide polymorphism in the viral polymerase gene that results in a coding change (D752 *vs.* N752) and is strongly associated with neuropathogenicity (D752) and high levels of viremia. However, strains containing each polymerase variant (D752 or N752) have the potential to cause EHM, and strict control measures should be taken regardless of the variant identified.

Infection with EHV-3 occurs through direct skin-to-skin contact during coitus or via secretions containing live virus (i.e., contaminated materials during artificial insemination, hands or even lips and nose of horses nuzzling or sniffing each other). No disruption of the skin barrier is necessary to establish infection and viral replication is typically limited to the stratified epithelium, leading to a localized inflammatory response associated with the classical cutaneous lesions. Spread of the virus to the underlying tissues and dissemination via the blood stream does not occur preventing systemic dissemination. Primary infection with EHV-3 often leads to secondary infection with *Streptococcus equi zooepidemicus* affecting the severity and duration of clinical disease. Most horses clear the infection on their own within 2–3 weeks of infection but a high percentage of horses establish latency, and recrudescence of the virus and clinical signs can be observed in horses in consecutive breeding seasons.

The exact pathogenesis of EHV-2 and EHV-5 is not fully understood. Infection with both viruses is likely acquired horizontally early in life usually by inhalation. The frequent isolation of EHV-2 from pharyngeal lymphoid tissue suggest that this might be a primary replication site from which the virus is then spread by peripheral blood leukocytes (PBL) to other organs. EHV-5 has recently been associated with EMPF. The pathogenesis is thought to mirror that of a murine model of lung fibrosis caused by MHV-68, marked by the progressive deposition of interstitial collagen, increased TGF- β and Th2 cytokine expression, and hyperplasia of type-2 pneumocytes.

The six equine herpesviruses are antigenically distincts although they share certain antigens. EHV-1, EHV-4, and EHV-9 are closely related antigenically, such that cross-neutralizing antibodies are generated. Also, EHV-2 and EHV-5 are closely related. Almost no data are available on the relationship of EHV-3 to other members of the equine herpesviruses, however, all of the EHV-3 are believed to share complement-fixing antigens.

Neutralizing antibodies are detected in the serum soon after an EHV-1 or EHV-4 infection. However, it has become clear that: (1) virus-neutralizing antibodies can reduce viral nasal shedding but do not correlate with protection from EHM or abortions, (2) protection from EHV-1 depends critically on induction of cytotoxic T-cell (CTL) responses and prevention of viremia, and (3) EHV-1 uses multiple mechanisms to evade the induction of protective immunity, providing a unique challenge for the development of preventatives. More recently there has been an increased interest in innate immunity to EHV-1 because early immunity is not only critically important for immediate protection but likely shapes subsequent adaptive immune responses. On the flip side, over the past years multiple immune evasion mechanisms employed by the virus have been identified. These include NK-cell lysis, alteration of cytokines regulating B- and T-cell responses, alteration of the chemokine network, interference with antigen presentation, inhibition of antibody dependent cytotoxicity, induction of T-regulatory cells and alteration of CTL responses. A number of EHV-1 candidate immunomodulatory genes have so far been identified. These include the UL49.5 and UL56/UL43 genes that interfere with MHC-I antigen presentation and induction of CTL responses, as well as glycoprotein G, which functions as a viral chemokine-binding protein that selectively inhibits IL-8 and CCL-3 mediated chemotaxis of phagocytes (neutrophils and macrophages). Other viral modulatory genes are likely present and may be identified in the future.

Immunity to EHV-2, EHV-3, EHV-5, and EHV-9 is poorly understood; however, virtually all horses have antibodies to EHV-2 and EHV-5 confirming the general apathogenicity of these viruses.

Clinical Features and Pathology

Clinical manifestations of EHV-1 and EHV-4 include primary respiratory disease, late term abortions, neonatal foal death, EHM and chorioretinopathy. EHV-4 infections are typically restricted to the respiratory tract but secondary disease has been reported occasionally. EHV-1 and EHV-4 respiratory disease can be mild or asymptomatic in older or previously exposed horses. In contrast, the respiratory disease observed in young immunologically naïve horses is often severe and lasts for 2–3 weeks. Infection is characterized by a short incubation time (<1 day), fever (39–41°C), which can last between 2 and 5 days, sometimes with a second spike approximately one week after the primary pyrexia and coinciding with the onset of viremia. Animals also suffer from serous nasal discharge and congestion of the nasal mucosa and conjunctiva. Less frequently, one can detect a transitory period of anorexia, enlargement of the submandibular lymph nodes and edematous swelling of the lower parts of the body and the extremities. An initial leukopenia is followed by leukocytosis before the temperature falls. Coughing is reported in cases with severe respiratory disease and occasionally in milder cases depending on the environment. Lower respiratory disease associated with secondary bacterial infection, tachypnea, anorexia and depression can be observed in young foals. Clinically EHV-1 and EHV-4 respiratory disease is difficult to distinguish, unless the virus is identified diagnostically.

EHV-1 is also the cause of late-term abortions and premature delivery of foals that die soon after birth. Mares infected with EHV-1 commonly do not display respiratory disease and abort 2 weeks to several months after infection or re-activation of the virus. Abortion typically occurs in the last trimester of pregnancy but has been reported as early as the second trimester. Abortions happen without warning signs and the placenta is often found together with the fetus, which has died from asphyxia or dies shortly after birth. Sporadic abortions in individual mares are most common, but EHV-1 outbreaks with attack rates >50% “abortion storms” have been reported and depend on herd management, immune status and viral factors. Mares typically recover and deliver a healthy foal in the next breeding season. Occasionally apparently healthy foals are delivered that become ill within 2 days of delivery and show respiratory distress, fever, failure to nurse, weakness, diarrhea and leukopenia and do not respond well to treatment.

Clinical signs of neurological disease caused by EHV-1 are highly variable and include head pressing, ataxia, and paralysis with complete recumbency. Both, EHV-1 and EHV-4 have been isolated from the central nervous system of infected horses, but neurological disease due to EHV-4 is extremely rare. EHV-1 does not invade the extravascular nervous tissue and is not neurotropic per se. Rather, the virus spreads from the respiratory tract to the CNS via infected leukocytes and infects endothelial cells of the blood vessels supplying the spinal cord. While the neurological form of the disease is usually lethal, some horses recover fully from neurological disease with no permanent neurological sequelae.

EHV-1 infection can also lead to chorioretinopathy causing permanent “shotgun” lesions in a substantial proportion of infected horses. A recent study has shown that >50% of yearling horses exhibit classical shotgun lesions following experimental infection with EHV-1, but that lesions are not visible *in vivo* until 1–3 months after primary infection. Lesions can be focal, multifocal or in rare occasions diffuse affecting the whole eye. Clinically, only diffuse lesions have a significant impact and cause loss of vision.

EHV-3 replication is restricted to the stratified epithelium of the skin or muco-cutaneous margins and lesions are restricted to the superficial skin of the external genitalia in both mares and stallions. An incubation period as long as 10 days can be observed following natural infection. The initial lesions are small (1–2 mm), raised, and reddened papules. The lesions then progress rapidly to the pustular form, and there is a general reddening of the vaginal mucosa in the mare. The number of lesions increases in the first few days, and by day 6, many of the lesions form ulcers up to 20 mm in diameter and 5 mm deep. Lesions can also be seen on the vulva, perineal skin, as well as the penis and prepuce of the stallion. The disease is usually mild such that the temperature, pulse, appetite and respiration remain close to normal. Occasionally, severely affected horses may be febrile and show depression and anorexia. Stallions may show a loss of libido and refusal to mount and mares may show frequent urination, arching of the back and vulvar discharge. The severity of the disease can be increased by secondary bacterial infections; however, uneventful cases are usually cleared within 2 weeks. EHV-3 is not abortigenic and does not lead to infertility.

The role of EHV-2 and EHV-5 in clinical disease is less understood. EHV-5 has been implicated as the cause of EMPF in recent years. EMPF is typified by low-grade fever, weight loss, and progressive exercise intolerance, along with radiographic evidence of nodular pulmonary interstitial fibrosis and isolation of the virus from affected lungs. EHV-2 has been associated occasionally with chronic throat infections. However, pharyngitis as well as conjunctivitis, coughing and nasal discharge has so far only been experimentally induced in young immuno-suppressed animals.

Infections with EHV-9 lead to encephalitis in horses under experimental conditions, but, more severely, in other species as well.

Respiratory disease caused by EHV-1 and EHV-4 results in inflammation, congestion and sometimes necrosis of the upper respiratory tract. Extensive swelling of the nasal mucosa may occur, and in later stages, the lungs may become involved. One can find typical herpesvirus inclusion bodies in the nuclei of the respiratory epithelium. The respiratory infection can become more serious if followed by a secondary bacterial infection, which may lead to bacterial pneumonia.

Fetuses that are aborted as a consequence of EHV-1 infection present with widespread hemorrhages and edema, as well as a yellowish discoloration of the fetal conjunctiva and splenomegaly – if virus is transmitted from mother to animal. Abortions without infection of the fetus also occur and the pathogenesis in the uterine vasculature largely resembles that of the vasculitis observed in the neurological form of the disease. The classic histopathology includes the presence of eosinophilic intranuclear inclusion bodies in various organs of the aborted fetuses. However, gross pathological and histopathological alterations are sometimes not as obvious and only sensitive methods (virus isolation, PCR, qPCR) are able to confirm the EHV-1 abortion. Classically, features associated with EHV-1 induced abortions differ in those fetuses aborted during the first 6 months of gestation

as compared with those aborted after 6 months. Those before 6 months present with widespread cell necrosis and inclusion bodies in the liver and lung. Those after 6 months exhibit jaundice, subcutaneous edema, excessive pleural fluid, pulmonary edema, splenomegaly and necrosis of the liver.

Similar to histopathological findings in the CNS and the pregnant uterus, vasculitis is common in the choroid of the eye, as are mild or moderate perivascular and interstitial infiltrates of lymphocytes and histiocytes around the chorioretinal vasculature.

Finally, vasculitis with perivascular to scattered interstitial lymphohistiocytic infiltrates can also be observed in the testis of intact males following experimental infection. In addition, occasionally, discrete lymphofollicular structures within the interstitium of the testes, tubular degeneration and arteritis in the fascia surrounding the testes or fibrous interstitium may be observed.

Tissues affected following an infection with EHV-3 include the vaginal and vestibular mucosa, penis, prepuce and the skin of the perineal region. One of the characteristics of an infection with EHV-3 is the sloughing of the surface epithelial cells. On occasion, the skin of the lips and mucus membranes of the respiratory tract may become involved, but the exanthema is usually mild.

EHV-2 and also EHV-5 infection becomes widespread throughout the body, and the viruses have been isolated from a variety of tissues. Horses affected by EMPF show coalescing or discrete nodules of fibrosis and an enlargement of bronchial lymph nodes. Histologically the lesions are centered on the alveolar parenchyma and are characterized by an expansion of collagen accompanied by infiltration of inflammatory cells into the interstitium.

Control

Standard diagnostic methods for equid herpesviruses are well established, including virus isolation, serological assays, particularly serum neutralization tests (SNT) and type-specific ELISAs, as well as molecular assays that are now almost exclusively based on quantitative PCR protocols.

A number of vaccines are available to combat EHV-1 infections, among them modified live vaccines (e.g., Rhinomune™ or Prevaccinol™), inactivated vaccines (e.g., Pneumabort K™, Equip™ EHV1,4, Prestige™, Prodigy™), inactivated combination vaccines, which – among others – also contain EHV-4 (e.g., Innovator™, Vetera™). Unfortunately, many EHV vaccines do not afford acceptable levels of protection, especially when inactivated combination vaccines are considered. All vaccines are given repeatedly to pregnant mares usually in the third, fifth, seventh and ninth months of pregnancy. To protect against viral rhinopneumonitis outbreaks, the vaccine is usually given to all horses every 3–6 months. There is considerable ongoing discussion as to proper vaccination against the neurological disease, which has become more prevalent during past years. Recent studies seem to suggest that modified live virus vaccines may be superior to especially inactivated combination vaccines with respect to duration of fever and virus excretion from the nasal mucosa; at this point there is however little evidence that vaccination can prevent EHM, and conflicting information is available on the use of vaccination for prevention of abortion. Clinical management often involves the use of antibiotics to prevent severe bacterial complications following the viral rhinopneumonitis. Because of the vaccine limitations, control of EHV-1 and EHV-4 infections involves isolation and quarantine of infected horses (up to 28 days) and sound hygiene for prevention of viral infection, since the viruses are highly contagious. Quarantine procedures are required with EHV-1 infections, since EHV-1 can lead to more serious disease of the CNS and the viruses can be spread easily in contaminated feed and water. In addition, minimizing stress and close contact of large groups of horses can prevent the spread of disease. It is important to recognize that EHV-1 infection is a reportable disease in some states of the U.S., and in these states, quarantine requirements will be determined by state officials.

No vaccines are available for preventing EHV-3 infection at present and unless secondary bacterial infection develops, genital lesions caused by EHV-3 infection usually heal without therapeutic intervention.

Future Perspectives

Considerable progress in unraveling the genetic makeup of EHV-1, EHV-2, EHV-3, EHV-4, EHV-5, and EHV-9 has been made during the last years, and the genomes have been sequenced in their entirety. With this information in hand, it will be possible to perform studies on gene expression and on proteins that are involved in virulence of each of the viruses. These studies will in turn open the possibility for a rational design of anti-EHV vaccines, especially against the most important pathogens, EHV-1 and EHV-4. These goals may be achieved by the use of viral deletion mutants that carry targeted gene deletions, which is greatly facilitated by the advent of a number of infectious DNA clones (bacterial artificial chromosome – BAC – clones) during the past years. Using novel molecular approaches, a better understanding of the viruses' biology will likely be possible in the near future and allow a finer definition of diseases caused by the different EHV.

Nomenclature

(H)/HA Hemagglutinin (subtype)
(N)/NA Neuraminidase (subtype)
HA0 Hemagglutinin polypeptide
HA1, HA2 Hemagglutinin subunits
HI Hemagglutination inhibition test
IAV Influenza A virus

M1/M2 Matrix protein 1/2
mRNA Messenger ribonucleic acid
NP Nucleoprotein
PA Polymerase acidic protein
PB1 Polymerase basic protein 1
PB2 Polymerase basic protein 2
vRNA Viral ribonucleic acid

Glossary

Antigenic drift The gradual accumulation of amino acid changes in the surface glycoproteins of influenza viruses.
Antigenic shift The sudden appearance of a novel combination of surface glycoproteins in a host as a result of reassortment.
Pandemic Outbreak of disease affecting a large region.

Reassortment The exchange of genome segments between distinct influenza A viruses (typically viruses of different subtypes).

Subtype Classification of influenza A viruses based on the antigenicity of the hemagglutinin and neuraminidase proteins.

Classification (Compact)

Most equine, canine and swine influenza viral infections are caused by influenza A viruses (IAV) in the *Influenzavirus A* genus of the family *Orthomyxoviridae*. Classification of viruses in this family is based on, but not limited to, the negative-sense and segmented nature of their RNA genome. Influenza A viruses (IAV) are further classified based on the antigenic reactivity of their surface glycoproteins hemagglutinin (HA) and neuraminidase (NA). Until recently, 16 HA (H1 to H16) and 9 NA (NA1 to NA9) subtypes of IAV viruses had been identified in different host species, with aquatic birds and primarily ducks being regarded as the reservoir hosts. Even though up to 144 possible subtype combinations of H1 to H16 and N1 to N9 are possible, only a few combinations have consistently been isolated from pigs, horses and dogs. Two additional subtypes of HA (H17 and H18) and NA (N10 and N11) have recently been identified in bats.

Consistent isolation of H1N1, H1N3 and H3N2 IAV from pigs suggests that these subtypes are associated with endemic infections. In addition, H2, H4, H5, H7, and H9 subtypes have also been reported to cause sporadic infections. There are only two subtypes of IAV known to be endemic in horses, H3N8 and H7N7, although the latter is now believed to be extinct. An equine-origin H3N8 virus and avian-origin H3N2 virus are currently circulating in dogs.

Although most cases of influenza virus infection reported in pigs, horses and dogs involve IAV, it appears that pigs at least can also be infected by other types of influenza viruses. Influenza C viruses (ICV), which are primarily human pathogens, have occasionally been isolated from pigs and the more recently discovered influenza D virus (IDV) was first isolated from pigs, although cattle are thought to be the major host.

As a general rule, the nomenclature of influenza viruses includes: the antigenic type of the virus (A, B, C or D); the host of origin for non-human isolates (e.g., swine, equine, canine); the geographical location of origin of the isolate; the viral strain or isolate number and the year of isolation; and the HA and NA subtype in brackets. For example, an IAV isolate obtained from pigs in Hong Kong in 2010 with the laboratory reference number 35 will be named: A/swine/Hong Kong/35/10 (H5N1).

Virion Structure

Mammalian IAV share the same morphological features. Virions are enveloped (with the viral envelope deriving from the host cell) and often pleomorphic. The diameter of spherical particles is around 80 and 120 nm, whereas filamentous forms of the virus often found in clinical isolates can reach up to 20 µm in length. The HA and the NA glycoproteins are inserted in the viral envelope in a ratio of approximately four to one (Fig. 1). The HA is a trimeric glycoprotein that binds to the cellular receptor during the entry stage of the virus. The NA protein, on the other hand, is a globular tetrameric glycoprotein. Additionally, another smaller integral matrix protein 2 (or M2 ion channel) is embedded in the envelope in a ratio of one M2 channel per 10–100 HA molecules. The lipid membrane is lined by another viral matrix protein (M1), which gives strength and rigidity to the viral envelope, which surrounds the viral genome.

Fig. 1 Influenza A virus structure of a virus particle and an RNA segment.

Genome

The IAV genome consists of eight negative-sense, single-stranded viral RNA (vRNA) segments encoding for around 12–14 viral proteins depending on the viral strain. In addition to coding regions, each viral segment also contains non-coding regions of various length at both the 5' and 3' ends. The distal 10–12 nucleotides of these non-coding regions appear to be highly conserved among the genome segments. These conserved regions allow the formation of “panhandle” structures (helical hairpins) by partial inverted complementarity between the 5' and 3' ends; this unique feature serves as a promotor for viral mRNA transcription and plays a critical role during genome replication and packaging. Additionally, the 5' non-coding regions include the messenger RNA (mRNA) polyadenylation signal, a uridine-rich region that serves as a template on which the viral polymerase stutters to generate the poly-A tail at the 3' end of each viral mRNA.

Viral ribonucleoproteins (vRNPs) consist of viral RNA segments covered with numerous copies of the nucleoprotein (NP) and a heterotrimeric RNA-dependent RNA polymerase complex composed of two “polymerase basic” (PB1 and PB2) proteins and one “polymerase acidic” (PA) protein. Within the virions, the vRNPs interact with each other and the M1 to form a “7 + 1” configuration with seven segments of different lengths surrounding a central segment, which is thought to play an important mechanistic role during genome packaging and virus budding.

Life Cycle

The virus life cycle can be broken down into six stages: (1) attachment and internalization; (2) fusion and uncoating; (3) mRNA synthesis and viral RNA replication; (4) translation; (5) assembly and packaging and (6) budding (**Fig. 2**).

Binding of IAV to the target host cell mainly occurs via the HA protein, which recognizes and binds to sialic acid (N-acetylneuraminic acid, Neu5Ac) residues that are attached to an underlying galactose sugar chain by α 2,3 or α -2,6 linkages on the surface of the host cell. After IAV particles are brought into the vicinity of the host cell surface, the HA and NA act co-operatively; HA binds cell surface sialic acid residues while NA locally degrades and removes unnecessary HA-sialic acid interactions. This creates iterative associations and dissociations of the HA with cell surface sialic acid residues, allowing the virus to ‘crawl’ across the cell surface. This probably ensures that the virus is directed to the right entry location on the cell surface, where HA-receptor mediated endocytosis will be triggered. Although it is still not clear whether binding of HA to sialic acid residues alone induces IAV internalization, induction of host cell signaling is required to direct IAV to its specific entry route and this certainly requires specific transmembrane receptors that mediate HA-receptor endocytosis. Additional host factors other than sialic acid residues have been identified as receptor determinants including C-type lectins and annexin V (A5). Virus particles are internalized via receptor-mediated endocytosis. Most virions are internalized via a clathrin-mediated endocytic process during which Epsin-1 is recruited to the binding sites of influenza viruses in synchrony with the assembly of clathrin-coated vesicles. Dynamin protein is then required for membrane fission, to pinch off the vesicles from the plasma membrane. Various studies have established that the virus can also infect cells via a clathrin- and caveolin-independent endocytic pathway showing all the characteristics of macropinocytosis. Recent

Fig. 2 Influenza A virus life cycle. 1 = Attachment and internalization; 2 = fusion and uncoating; 3 = mRNA synthesis and viral RNA replication; 4 = translation; 5 = assembly and packaging; and 6 = budding. Adapted from Neumann, G., Noda, T., Kawaoka, Y., 2009. *Nature* 459, 931–939.

approaches based on single-virus tracking and imaging established that both clathrin-mediated and clathrin-independent pathways lead to efficient viral fusion.

Following internalization of the virus, virions are initially transported from the cell periphery to early endosomes and then transferred to late endosomes where a late acidification step occurs. This low endosomal pH (≈ 5) triggers a conformational change in the HA protein of the virus, which exposes the 23 residues near the N-terminus of HA2, also known as the fusion peptide. The HA is synthesized as a precursor protein (HA0) and must be cleaved into HA1 and HA2 by host proteases in order to be infectious. At neutral pH, the fusion peptide is hidden in a hydrophobic pocket in the HA2 trimeric interface. The exposed fusion peptide inserts into the endosomal membrane on the N-terminus of HA2 while its C-terminus remains anchored to the viral membrane. HA2 trimers then bend back on themselves in a hairpin-like conformation, bringing both membranes close to each other to merge the two outermost leaflets of both membranes (often referred to as hemifusion). Subsequently, the lipid stalk ruptures to form a fusion pore, which in turn activates the M2 ion channel. Hydrogen ions from the endosome are then pumped into the viral core via the M2 ion channel, creating an internal acidification of the virions, which disrupts protein–protein interactions that hold the viral core together and causes the release of the vRNPs from the M1 into the cytoplasm via the fusion pore.

Replication of IAV takes place in the cell nucleus. After vRNPs are released into the cytoplasm, nuclear localization sequences (NLS) exposed on NP molecules recruit the cellular adapter protein importin- α . Importin- α then binds to the importin- β transport receptor and the entire complex directs the vRNPs to the nuclear pore complex, via which vRNPs are released into the nucleus. Replication and transcription are carried out by the viral RNA-dependent RNA polymerase complex made up of the PB1, PB2 and PA proteins. Because this complex is an integral part of each vRNP imported into the nucleus, each vRNP becomes an independent functional unit of replication and transcription. Given the negative sense nature of the genome, vRNA replication begins with an initial step of transcription, where vRNPs are transcribed into a complementary RNA (cRNA), which is then used as template for the synthesis of new vRNAs. As opposed to cRNA synthesis, influenza viral mRNA transcription is a unique primer-dependent transcription process during which the viral polymerase complex, recruited to the promoter-associated Pol II, binds the 5' cap of cellular mRNAs via its PB2 sub-unit. Subsequently, the PA sub-unit, containing the endonuclease activity, cleaves cellular mRNAs approximately 10 to 13 nucleotides from their 5' end. The PB2 cap-binding domain then rotates to position the stolen cellular capped primer sequences into the catalytic site of PB1, where it is then used as a primer for elongation of the mRNA, using vRNA as a template. Viral transcripts are then polyadenylated by a stuttering process of the polymerase on a short poly-U sequence located at the 5' end of the viral RNA. The coding capacity of IAV is enhanced by the presence of donor-acceptor splice sites. As a result, during mRNA transcription, these viral transcripts are capable of recruiting the cellular spliceosome machinery to produce additional spliced transcripts such as the M2 and the NEP. A third transcript of the NS gene segment (NS3) in which the donor/acceptor splice site exhibits a novel GC/GUA motif was recently identified.

The newly synthesized vRNPs are selectively exported out of the nucleus. It is thought that the viral nuclear export protein (NEP), via its leucine-rich nuclear export signals, plays a central role in targeting vRNP complexes to the chromosomal maintenance 1 (CRM1) nuclear export pathway, but nuclear export signals also exist in M1 protein and NP. Nuclear export of capped IAV mRNAs is believed to occur in an analogous manner to the nuclear export of cellular mRNAs. It is believed that following capping, the 5' caps of nascent viral transcripts bind to the cap-binding complex. The viral NS1 protein recruits proteins involved in nuclear export of cellular mRNAs but also forms inhibitory complexes with some essential export factors (such as Nxt1) to block the export of endogenous cellular mRNAs, as a way to ensure the preferential nuclear export of viral transcripts.

Viral enveloped proteins (HA, NA and M2 for IAV) are synthesized on membrane-bound ribosomes into the endoplasmic reticulum where they are folded and trafficked to the Golgi apparatus for post-translational modifications, whereas PB1, PB2, PA, NP, NS1, NS2 and M1 synthesis is carried out by cytosolic ribosomes. NP, PB1, PB2 and PA proteins are synthesized during early infection. The NLS sequences on these proteins target them back into the nucleus by the recruitment of importin- α and - β to assist in viral mRNA transcription and viral replication. In addition to generating new transcripts by alternative splicing, IAV also generates so-called accessory proteins by either alternative translation initiation sites or ribosomal frameshift. Segment 2, for instance, additionally encodes for PB1-F2 and PB1-N40 (depending on the viral strain) by using alternative translation initiation sites. Likewise, segment 3 can also encode for PA-X (a fusion protein that results from a +1 ribosomal frameshift), while PA-N155 and PA-N182 are N-terminally truncated forms of PA.

Viral RNPs are trafficked toward the apical plasma membrane in polarized epithelial cells. The M1 protein has also been identified as a key component in the assembly process of virions via protein-protein interactions. M1 is thought to interact with itself, the vRNPs, and the HA and NA surface glycoproteins to both facilitate the concentration of viral components at the budding site and allow the discrimination of viral proteins from host proteins. By interacting with the cytoplasmic tail and the trans-membrane domain of envelope glycoproteins HA and NA, M1 functions as a bridge between the viral envelope and vRNPs.

It is believed that budding of IAV occurs at distinct apical plasma membrane regions known as rafts. It has been suggested that IAV promotes budding by inducing membrane curvature. The expression and abundance of HA and NA on one side of the membrane are sufficient to induce budding, and the presence of M1 greatly increases budding efficiency. It is thought that M1 oligomerizes upon reaching the cellular membrane where it is modeled to form curved structures. This property could explain its role in the formation of either spherical or filamentous virion forms. To facilitate the release of virions from the plasma membrane, NA catalyzes the hydrolysis of glycosidic linkages that attach sialic acids to underlying sugar molecules. The sialidase catalytic site is located in a highly conserved deep pocket in the center of each monomer of the NA tetramer.

The segmented nature of the genome means that IAV viruses can undergo reassortment, i.e., when more than one virus infects a single host cell a virus with a different combination of genome segments can arise. Antigenic shift occurs if the reassortant virus generated has a novel combination of HA and NA proteins. The lack of proofreading enzymes associated with RNA replication results in a high frequency of mutation. Together with high rates of replication, this enables IAV to evolve rapidly. The process of antigenic drift results from the accumulation of amino acid changes in the HA and NA proteins that enable the virus to escape neutralization by pre-existing antibody.

Epidemiology

Three major subtypes of IAV circulate in the pig population worldwide. The H1N1, H3N2 and H1N2 subtypes are often associated with acute respiratory disease in pigs and, in some cases, with more chronic, multifactorial respiratory disease problems in combination with other viruses or bacteria. Although the same subtypes circulate in Europe and the USA, their genetic evolution is significantly different between continents. In Europe, H1N1 subtypes were introduced into the pig population from wild ducks. In contrast, two lineages of H1N1 circulate in the USA; the 'classical' H1N1 (cH1N1) lineage was first identified in 1930 is also found in Asia and the 'reassortant' H1N1 (rH1N1) viruses with HA and NA of cH1N1 and the internal proteins of a recently emerged H3N2 subtype virus.

In European swine, circulating H3N2 viruses are reassortants of the classical H1N1 (avian-like) virus with the human H3N2 (avian-like HA and NA with internal genes from human H3N2 virus). In a separate reassortment event, the swine (avian-like) H1N1 viruses also gained the human N2 gene, generating a novel H1N2 reassortant, now endemic to Europe. Although different lineages of human H3N2 have also been detected in pig populations in Asia, these lineages seem to undergo less antigenic drift compared to their ancestral human lineages. In contrast to Europe, the H3N2 virus circulating in North American swine is a triple reassortant containing: HA, NA and PB1 of human origin; NP, M and NS genes originating from the classical swine H1N1; and PA and PB2 genes of north American avian virus origin. These triple reassortants are believed to have further acquired HA genes of diverse origins, leading to the appearance of the triple reassortant H1N2 virus (acquiring its HA from the classical swine H1N1). Other reassortant swine viruses have been reported in Europe (H1N7), Asia (H3N1) and the USA (H2N3) and some that only transiently affect pigs in other parts of the world (H9N2, H3N6 and H5N2). Novel reassortants of swine viruses with equine IAV have also been reported, highlighting the role swine play in the generation of new influenza viruses. The fact that most swine IAV are reassortants, usually of avian and human IAV, led to the hypothesis that swine serve as 'mixing vessels' for IAV through which novel viruses can be transmitted to man. The 2009 influenza pandemic caused by an H1N1 virus that originated in pigs and was a reassortant with genome segments from several viruses circulating in swine. Since the 2009 pandemic, further reassortant viruses of the 2009 H1N1 pandemic virus and other IAV strains circulating in pigs have been detected in many different countries.

Two subtypes of IAV have circulated endemically in equids: H7N7 and H3N8. The prototype equine H7N7 virus was isolated from horses in Prague in 1956 when it was termed 'equine subtype 1'. There is little evidence that H7N7 viruses are still circulating in the equine population. Virus of the H3N8 subtype was first isolated from horses in 1963. The virus is thought to have emerged in South America, spreading northwards and subsequently almost worldwide. The equine H3N8 viruses were initially a single lineage, which later evolved into two lineages (American and Eurasian). The Eurasian lineage, composed of viruses isolated from horses in Europe and Asia, continues to form a single lineage, whereas the American lineage has further diverged into three sublineages: 'South American', 'Kentucky', and 'Florida'. Viruses in the Florida sublineage further evolved into two clades. Florida clade 1 (FC1) viruses predominate on the American continent but have also caused large outbreaks in Africa, Australia, Europe, Asia and South America. Florida clade 2 (FC2) viruses, on the other hand, predominate in Europe, but viruses from this clade have also been isolated in Asia and North America. Overall, viruses in the Florida sublineage have dominated since its emergence. Equine IAV of the H3N8 subtype is endemic in many American, European and Asian countries and occasionally causes epidemics. The most recent noteworthy epidemic of equine IAV was in Australia in 2007/2008. Australia had previously been free from equine IAV and succeeded, at great expense, in eradicating it within 6 months of its emergence. Sporadic infection of equids with other IAV subtypes occurs rarely. A highly pathogenic avian influenza of the H5N1 subtype was isolated from donkeys living in close contact with diseased birds. It was thought that transmission of IAV from horses to other species was unlikely until transmission of the equine H3N8 virus to dogs occurred. Here is some evidence that the equine H3N8 subtype may have occasionally caused human infection in people but experimental infection of human volunteers with equine IAV was largely unsuccessful.

Historically, there were occasional reports of sporadic transmission and sub-clinical infection of dogs with IAV of human origin with no evidence of onward transmission. More recently, two subtypes of IAV (H3N8 and H3N2) have become established in dogs. The canine H3N8 virus is believed to have originated from horses. The virus was first isolated in 2004, but retrospective serological investigation suggested it had been circulating among greyhounds for some years prior to its identification. The canine H3N8 virus spread to other dog populations throughout the USA, mainly affecting dogs housed in large groups, e.g., dogs in animal shelters, boarding kennels and day-care centers. However, by 2018, the canine H3N8 virus seemed to have mostly died out, being limited to one large rescue center. A closely related virus was identified as the cause of an outbreak of respiratory disease among a group of foxhounds in the UK in 2002 and some dogs became infected during the large outbreak of equine H3N8 IAV in Australia in 2007/2008. However, the virus did not become established in dogs in Australia or the UK.

The second canine IAV subtype originated from birds. The virus is reported to contain gene segments from several different avian subtypes. Infections with this subtype were first reported in South Korea, where dogs are farmed for meat, and spread to other Asian countries including China and Thailand. The virus was introduced into the USA in 2015, presumed to be due to importation of dogs rescued from the Far East. It was first identified in an animal shelter in Chicago and spread to other states within the USA far more rapidly than the H3N8 subtype had done.

Dogs are sporadically infected with other types of IAV but these are not maintained in dog populations. An Asian lineage of a highly pathogenic avian influenza (HPAI) H5N1 virus was detected in a dog that had scavenged carcasses of chickens infected with the virus in Thailand. Antibodies were detected in other dogs, but no transmission of disease to in-contact dogs was observed. Other rare reports of avian subtypes of IAV affecting dogs include an HPAI H5N2 virus and H9N2 viruses. In a worrying development, an H3N1 virus was recently isolated from a dog with respiratory disease in Korea. This virus appeared to be a reassortant between an endemic canine H3N2 virus and the human 'pandemic' H1N1 subtype.

Pathogenesis

Influenza A virus infection in pigs, horses and dogs is a disease of the upper respiratory tract. There is usually a short incubation period (2–3 days). The virus replicates in epithelial cells, leading to disruption of the mucociliary elevator, which is one of the factors that predisposes to secondary bacterial infection. Both host and virus factors (particularly the HA, polymerase proteins and NS1) contribute to IAV pathogenesis. As described above, proteolysis is required to cleave the inactive HA0 protein into the HA1 and HA2 subunits. In the endemic porcine, equine and canine viruses, the HA0 is cleaved by trypsin-like proteases found in the gut and respiratory tract that recognize a single arginine in the cleavage site (a monobasic cleavage site). The acquisition of a multi-basic cleavage site in avian H5 and H7 subtype IAV during infection of chickens means that these viruses can be cleaved by ubiquitously expressed subtilisin-like proteases. This is one reason why HPAI viruses can cause severe and often fatal systemic infection in various species. Mutations in the polymerase complex proteins can contribute to IAV pathogenicity by enhancing transcription and replication of the viral genome. The NS1 protein is a highly multifunctional protein that is important for efficient virus replication and also modulates the host's innate immune response.

The type of sialic acid linkage in the host cell receptor of IAV has been shown to affect the HA receptor binding affinity in a host-specific manner leading to the suggestion that species-specific differences in the distribution of linkages on the respiratory epithelial cells influences the ability of IAV to transmit between species. The detection of both α 2,3 and α -2,6 linkages in the pig respiratory tract was thought to be central to the role of the pig as a bridging host by enabling the co-infection of pigs with avian and human IAV leading to the generation of reassortant viruses. However, several studies have demonstrated that HA receptor-binding preference for a specific sialic acid linkage is not essential for infection but is more critical for virus transmission. Mutations in the HA can alter the receptor binding affinity and therefore adaptation of IAV to a new host. Indeed, a tryptophan (W) to leucine (L) mutation of residue 222 of the HA was associated with adaptation of both the equine H3N8 and avian H3N2

viruses to dogs. However, interspecies transmission is not solely due to adaptive mutations in the HA and NA proteins. The virus must also overcome intrinsic and innate immune restrictions to replicate in a novel host. For example, interspecies transmission of avian IAV to mammalian hosts requires adaptation of the viral polymerase complex to a different importin- α isoform. Several recent studies have shown that differences in the pH stability of the HA protein reflect adaptation to different host species. A more pH-stable HA protein allows the virus to survive longer in mildly acidic environments and during infection, membrane fusion occurs in late rather than early endosomes. Avian IAV typically have a pH of activation of >5.5 whereas viruses that replicate in the upper respiratory tract of mammals generally have a pH of activation of ≤ 5.5 . Swine IAV have a broad range of pH (5.3–6.0), suggesting that pH of activation of the HA is another factor contributing to the role of pigs as a bridging host for adaptation of avian viruses to human hosts. Furthermore, porcine respiratory epithelial cells have a lower interferon response to IAV infection than equivalent human cells, which may also contribute to the lower barrier to infection of pigs with IAV from other species.

Clinical Features

The clinical signs of IAV infection are similar among pigs, dogs and horses. Typical signs include high fever, cough, nasal discharge, anorexia and apathy. Morbidity rates are usually high, but animals typically recover after 2–6 days. Although the mortality rate is typically low (less than 1%), the disease can be exacerbated by the development of secondary bacterial pneumonia.

Diagnosis

Although a rapidly spreading febrile respiratory disease characterized by sudden onset of repeated coughing is very suggestive of IAV infection in pigs, horses and dogs, the clinical signs are not pathognomonic and are often suppressed in animals that become infected despite being vaccinated. Laboratory confirmation is therefore necessary. Detection of virus in clinical specimens (nasopharyngeal swab or nasal or tracheal wash samples) is usually achieved by RT-PCR, typically using primers for the more conserved matrix or nucleoprotein genes. This approach is more rapid and sensitive than virus isolation, but isolation of viruses remains important to fully characterize circulating viruses. Viral shedding is typically limited to day 2–4 post infection, declining rapidly during the clinical phase (Fig. 3). Therefore, to optimize the likelihood of obtaining a positive result, samples for virus detection or isolation should be obtained within 1–2 days of onset of clinical signs and/or from other animals in contact with the index case. Serological assays are important to confirm infection both as a diagnostic aid for ongoing cases and for surveillance purposes. The World Organization for Animal Health (OIE) recommends the hemagglutination inhibition (HI) test. The assay is based on binding of antibodies to a standardized dose of virus inhibiting its ability to agglutinate red blood cells. A variety of factors can affect the sensitivity and specificity of the test. For canine, equine and porcine influenza, receptor-destroying enzyme and periodate and heat treatment are used to inactivate non-specific inhibitors in serum and the test typically uses 0.5 or 1% chicken or turkey red blood cells. As there may be pre-existing antibodies (from previous infection or vaccination), paired serum samples should be taken, with a 4-fold increase of titer between an acute phase sample and a convalescent sample taken 10–21 days later usually taken to indicate recent infection (Fig. 3). Competitive ELISA for detection of antibodies to nucleoprotein are also increasingly used to diagnose influenza infection.

Treatment

Although three classes of influenza antivirals (inhibitors of the M2 matrix protein, neuraminidase and PA polymerase) are licensed for human use, treatment for veterinary species is largely supportive. Treatments include fluids to help maintain hydration or

Fig. 3 Optimal sampling times for diagnosis of influenza A virus infection.

correct dehydration, non-steroidal anti-inflammatory drugs to reduce fever and inflammation and antimicrobials for known or suspected secondary bacterial infections.

Prevention

Inactivated virus vaccines are commercially available for use in pigs. In the US, it is recommended that autogenous vaccines are considered if the strains in commercially-available vaccines are not a close match for circulating strains, but autogenous vaccines are only permitted for use on the farms for which the vaccine was generated.

Inactivated virus vaccines against equine IAV first became available in the late 1960s, shortly after the first human IAV vaccines were developed. Subsequently, subunit ('split') vaccines were introduced. Today, a range of different equine IAV vaccines is available; whole inactivated virus, subunit immune-stimulatory complex (ISCOM/ISCOMatrix), live attenuated and recombinant live vector. The live canarypox-vectored vaccine expresses only the HA protein of IAV HA enabling a differentiation of infected from vaccinated animals (DIVA) strategy to be adopted in combination with an ELISA to detect antibodies to NP, which is not present in the vaccine. Demonstration that vaccine effectiveness is compromised if vaccine strains are not updated periodically led to the formation of an OIE (World Organization for Animal Health) Expert Surveillance Panel on Equine Influenza Vaccine Composition, which meets annually.

The first vaccine to protect dogs against the H3N8 IAV strain was launched in 2009 in the USA. Vaccines were developed against the H3N2 IAV soon after it emerged and there is currently a bivalent vaccine available containing both H3N8 and H3N2 strains in the USA.

Concluding Remarks

Swine, equine and canine IAV have been referred to as 'neglected influenza viruses'. It is unlikely that the characteristics of the next pandemic IAV, or where it may emerge from, can be accurately predicted therefore, surveillance of IAV strains circulating in these neglected species is of paramount importance.

Feline Calicivirus (*Caliciviridae*)

Margaret J Hosie and Michaela J Conley, MRC-University of Glasgow Centre for Virus Research, Glasgow, United Kingdom

Classification

Feline calicivirus (FCV) is a non-enveloped, single stranded, positive sense RNA virus classified within the *Vesivirus* genus of the *Caliciviridae*. Vesiviruses have been shown to infect and cause varying clinical signs among many animal species. FCV was originally isolated in 1957 in New Zealand from cells in culture and has been shown to cause respiratory illness among felids. FCV was originally classified as a picornavirus (known as feline picornavirus for some time) prior to amendment and inclusion within the vesivirus genus of the *Caliciviridae* family. The *Caliciviridae* family was first classified in the third report of the International Committee on Taxonomy of Viruses (ICTV) in 1979. Calicivirus is derived from the latin word for cup, *calix*. The classification was due to the use of a single capsid protein which assembled to form icosahedral particles of 30–40 nm in diameter with 32 cup-shaped depressions on their surface.

Virus Characteristics

In the 1970s, small individual particles of 35 nm in diameter were observed in FCV infected cells by electron microscopy. FCV particles were also seen in association with smooth membranes within cells.

The major capsid protein of FCV, VP1, assembles into capsomeres that form arch-like structures on the surface of the virus, giving rise to the characteristic cup-shaped depressions on the virus particle. The VP1 dimer conformations differ slightly, forming A, B and C isoforms. A/B (bent) and C/C (flat) capsomeres assemble at different positions in the viral particle which results in $t=3$ icosahedral symmetry with 180 subunits (Fig. 1). A/B capsomeres are assembled around the five-fold symmetry axes while C/C capsomeres are located at two-fold symmetry axes (resulting in the alternation of A/B and C/C capsomeres around the three-fold symmetry axes).

The major capsid protein VP1 comprises 3 domains: the shell (S) domain forms the floor of the capsid, P1 makes up part of the viral spikes and P2 (which is an insertion into P1) forms the outer surface of the capsid protrusions and has a role in binding the cellular receptor molecule as well as neutralising antibodies (Fig. 2). The S domain of VP1 contains an eight-stranded β -barrel structure, with strands designated B to I. These strands form two, four-stranded β -sheets (composed of strands BIDG and CHEF) as well as two alpha helices between strands C–D and E–F. The P domain is joined to the S domain via a flexible hinge region, allowing slightly different conformations to be adopted by the A, B and C VP1 isoforms. The P2 domain contains a six stranded β -barrel (A' to F') of varying lengths and positions, as well as a hyper-variable region that is responsible for the variation observed between strains. These hypervariable regions form neutralising epitopes which serve as targets for the host's immune system.

All members of the *Caliciviridae* family are morphologically similar to FCV, although the P2 domains of VP1 can differ, as shown in Fig. 3. For example, some capsomeres form rounded structures e.g., rabbit haemorrhagic disease virus and norovirus GII.10, while other caliciviruses, including FCV, form rhomboid structures.

Genome Organisation and Viral Proteins

FCV encodes a 7.7 kb single stranded, positive sense RNA genome with a VPg protein covalently linked to the 5' end and a 3' polyA tail. An additional RNA species of 2.4 kb (known as subgenomic mRNA) is also produced during infection which

encompasses the coding region of the structural proteins of the virus. FCV encodes three open reading frames (ORFs), ORF1 encodes the non-structural proteins, ORF2 encodes the major capsid protein, VP1, while the minor capsid protein, VP2, is encoded on the third ORF (**Fig. 4**).

The major capsid protein, VP1, forms the majority of the viral capsid (180 copies per particle) with the minor capsid protein, VP2, incorporated to a lesser extent.

The subgenomic RNA forms the template for translation of VP1 which forms a 76 kDa precursor that is subsequently cleaved to yield the mature capsid protein of 62 kDa. This cleavage of VP1 is mediated by the viral protease and is essential for the life cycle of FCV. The leader of the capsid protein (LC) is cleaved post-translationally and has been shown to cause the cytopathic effect

Fig. 4 Genome organisation of FCV. Diagrammatic representation of the open reading frames (ORF) and proteins encoded by the FCV genome and the two RNA species produced during infection.

observed in infected cells. Many viral products form protein-protein interactions. VP1 has been shown to interact with VPg, the protease-polymerase (NS6–7) as well as the minor capsid protein, VP2.

The minor capsid protein, VP2, is crucial for viral replication and release of progeny viral particles. Each virion is predicted to incorporate one or two copies of VP2, which is involved in the self-assembly of the capsid.

Non-structural proteins

Almost all of the non-structural proteins of FCV associate with membranous replication complexes in infected cells, where translation and viral genome replication are co-ordinated. These proteins include NS2, NS3 (helicase) and NS6–7 (protease-RNA dependent RNA polymerase).

Virion protein g (VPg/NS5) is a small protein that is not required for FCV infection, although it is essential for translation of the viral RNA (unless replaced with a cap structure). Polypyrimidine tract binding protein (PTB) is redistributed by FCV to the cytoplasm (from the nucleus), where it interacts with both the genomic and subgenomic viral RNAs via their 5' ends. PTB has been shown to partly co-localise with FCV replication complexes and provides a switch from translation to viral genome replication. VPg is also associated with NS4 in replication complexes which suggests a role in anchoring the small VPg protein near the complexes for close proximity during viral RNA replication.

NS2 interacts with NS3, NS4 and NS6–7 in the membranous replication complexes. NS2, NS3 and NS4 have been proposed as possible transmembrane proteins which localise to the endoplasmic reticulum and may result in membranous rearrangements which are characteristic of FCV infection. NS3 has the ability to prevent the activation of IRF3 (interferon response factor-3) and therefore plays a role in the suppression of the innate immune response during FCV infection.

The FCV protease/polymerase (NS6–7) forms oligomers and interacts with VPg as well as ORF2 (encoding VP1). A weak interaction with VP2 has also been described. The viral polyprotein is cleavage in *cis* by the FCV protease to yield the individual non-structural proteins, however, the protease-polymerase (non-cleaved protein) is thought to be the active form of the RdRp. Nucleolin is essential for FCV replication and interacts with both viral RNA and the protease-polymerase. NS6, appears to reduce cellular translation through the cleavage of poly A binding protein (PABP) and has recently been shown to also impair the formation of stress granules within infected cells.

Life Cycle

FCV infection is restricted to cells of feline origin although this can be overcome by transfection of viral RNA into cells, indicating that the restriction occurs at the stage of binding and entry rather than replication. Attachment of FCV to cells is most efficient at pH 6.5 and occurs as quickly as 15 min post cell exposure. The entry of FCV is pH dependent; the low pH generated by the

Fig. 5 Three-dimensional reconstruction of FCV decorated with fJAM-A. Cryo-electron microscopy and three-dimensional reconstruction were used to solve the structure of FCV (F9 strain; cyan and pink) decorated with the soluble ectodomain of fJAM-A (magenta) at 3.5 Å resolution. Image provided by Dr. Michaela J. Conley and Dr. David Bhella (MRC-University of Glasgow, Centre for Virus Research).

acidification of endosomes is essential for the uncoating of FCV and the release of the viral RNA into the host cell before replication can ensue. The entry of FCV is dependent upon clathrin mediated endocytosis and the release of the viral genome is likely mediated by the permeabilisation of membranes during FCV entry.

Many viruses utilise carbohydrate moieties (e.g., sialic acid) as attachment factors or as parts of their receptors. Neuraminidase treatment of feline cells (to cleave terminal sialic acid residues) reduced the binding of FCV to cells by approximately 23%, suggesting a potential role of sialic acid in FCV attachment and entry. FCV binds to α 2,6-linked sialic acid (but not α 2,3-linked), which is thought to be present on an N-linked glycoprotein on the surface of susceptible cells. This sialic acid linkage preference could contribute to tissue specificity and cell tropism.

The functional receptor for FCV is feline junctional adhesion molecule A (fJAM-A), which is found at tight junctions between epithelial and endothelial cells. JAM-A can also be found on platelets and leucocytes, as described for both the murine and human JAM-A proteins. FCV infection results in the re-localisation of fJAM-A from tight junctions into the cytosol of the cell. Antibodies targeting JAM-A have been shown to reduce FCV binding to Crandell-Reese feline kidney cells, while the expression of fJAM-A in non-permissive cells rendered them susceptible to infection with FCV. JAM-A contains a short cytoplasmic tail, a transmembrane region and an ectodomain (composed of sub-domains D1 and D2). D1 of fJAM-A is sufficient for FCV attachment and feline JAM-A shares over 75% amino acid identity with its human counterpart. Feline JAM-A contains a predicted N-glycosylation site at position 185, based on this sequence identity.

All fJAM-A domains are necessary for infection with FCV although the PDZ-binding motif (within the cytoplasmic domain of fJAM-A) is not required for virus entry. FCV is able to interact with both monomeric and dimeric forms of fJAM-A with residues D42, K43 and S97 (in D1 of the fJAM-A ectodomain) being important for virus binding. FCV binds both monomeric and dimeric fJAM-A, since the virus binding site and fJAM-A dimerisation site are located at distinct regions/faces of the fJAM-A ectodomain.

The structure of FCV bound to the fJAM-A ectodomain has been determined by cryo-electron microscopy and three-dimensional reconstruction (**Fig. 5**). Binding of fJAM-A to FCV appears to trigger a conformational change in the capsid resulting in the anti-clockwise rotation (15°) of the VP1 capsomeres. Two fJAM-A proteins bind to two VP1 proteins (a single VP1 capsomere) in a head-to-tail manner (i.e., the D1 domain of the first fJAM-A protein lies adjacent to D2 domain of the second fJAM-A protein). The fJAM-A proteins also appear to bind to FCV in their monomeric form. The conformational change observed upon fJAM-A binding likely acts as a priming step for virus entry into the host cell via clathrin-mediated endocytosis.

Epidemiology

FCV is widespread in the domestic cat population, it has been isolated from up to 24% of healthy cats at cat shows and 10% of cats attending veterinary surgeries. The prevalence increases as the number of cats in a household increases, with the highest prevalence observed in large groups of cats housed together in multi-cat households. As many as 25%–40% of cats kept in colonies and shelters are infected, whereas the prevalence in small groups of cats is approximately 10%. The prevalence amongst colonies can range from 50% to 90%.

FCV is host-specific; there are no known reservoirs or alternative hosts and the virus does not infect humans. FCV-like viruses have been isolated from dogs, although it is unlikely that such viruses play a role in the epidemiology of FCV infection. Following infection of cats, FCV is shed in the oral and nasal secretions. The majority of cats shed virus for more than 30 days, although shedding can last for weeks or even several years after the acute clinical signs have resolved.

Pathogenesis

Cats become infected via the nasal, oral or conjunctival routes and the primary site of viral replication is the oropharynx. A transient viraemia occurs 3–4 days following infection and during this period the virus can be detected in many other tissues.

Following acute infection, the virus induces necrosis of epithelial cells and vesicles are observed, typically on the margin of the tongue. The vesicles subsequently develop into ulcers and it has been demonstrated that the dermis becomes infiltrated with neutrophils in the affected regions before the mouth ulcers resolve 2–3 weeks later. Occasionally other tissues are infected, such as the lungs and joints. Focal alveolitis can occur, leading to acute exudative pneumonia and proliferative interstitial pneumonia and lameness has also been observed, with acute synovitis and thickening of the synovial membrane.

The recent emergence of highly virulent systemic strains of FCV (VS-FCV) has been reported in the US, Europe and the UK. Unlike the majority of FCV infections, VS-FCV infected cats develop severe, diverse lesions, including cutaneous oedema and ulcerative lesions on the skin and paws, hepatic necrosis, pancreatitis, pulmonary oedema and disseminated intravascular coagulation. Outbreaks usually occur in multi-cat environments and have been characterised by rapid onset and high mortality. It has been reported that VS-FCV strains emerge independently from genetically distinct FCV strains but attempts to identify genetic patterns within the viral genome that define the highly virulent FCV biotype have been inconclusive so far. The pathogenesis of virulent systemic FCV infection might also include immune mediated components and/or environmental and management factors.

Following recovery from acute disease, the majority of cats clear FCV infection within approximately 30 days, although some cats can shed virus for longer. In healthy carrier cats, FCV is localised within the tonsillar epithelium, but, since tonsillectomy does not terminate the carrier state, it is likely that the virus also persists in other sites. It has been postulated that amino acid mutations in the viral capsid protein might lead to the appearance of FCV variants that escape the host immune response and persist within infected cats.

Control and Prevention

Disease Control

FCV particles can survive for up to 2 weeks on solid surfaces and are stable between pH values ranging from 4 to 8.5 and the virus is resistant to many common disinfectants. Effective disinfectants include sodium hypochlorite (5% bleach diluted at 1:32), potassium peroxy-monosulfate, chlorine dioxide and commercial products that have been approved for their virucidal activity. FCV infections often arise in cat shelters, but virus transmission can be limited, or even prevented, by appropriate shelter design and by instigating management measures to avoid cross infection of cats. For example, cats should be housed individually, only cats originating from the same household should be allowed to mix and flea control should be implemented to minimise the risk of transmission of FCV and other diseases. New cats arriving in shelters that are healthy should be vaccinated as soon as possible, preferably with a modified live virus vaccine to induce protection more rapidly.

FCV can be a major problem in breeding catteries, characterised by upper respiratory disease in kittens as young as 4–8 weeks of age, coinciding with the waning of maternally-derived antibodies. FCV infection can be severe in young kittens, often affecting all kittens in affected litters and some kittens may develop pneumonia and die. Breeding queens should be vaccinated so that kittens acquire high levels of maternally-derived antibody via colostrum and milk, which will protect them from FCV infection for several weeks. It is recommended that breeding queens should be vaccinated prior to mating rather than during pregnancy. Modified live virus vaccines are not licensed for use in pregnant cats and only inactivated vaccines should be used. The earliest age for which FCV vaccines are licensed for kittens is six weeks, but vaccination could be considered in younger kittens if they are at risk of infection. Alternatively, early weaning from four weeks of age will protect kittens against infection from infected breeding queens.

Vaccination

Both modified live and inactivated parenteral FCV vaccines are available. Modified live intranasal vaccines can still be used in US but are not available in Europe. It is thought that FCV vaccines provide protection mainly via the induction of virus neutralising antibodies, although cellular immunity has not been extensively examined following either FCV vaccination or infection. As FCV rapidly mutates and gives rise to viral variants, it has been suggested that field isolates could evolve and become resistant to vaccines based on strains that have been used for several decades; indeed, vaccine manufacturers are seeking to identify and introduce newer vaccine strains that might provide wider cross protection. At present, the most commonly used vaccine strains are F9 (the oldest strain that was isolated in the 1950s), FCV 255 and two more recent strains, G1 and 431.

Several *in vitro* studies have provided evidence that older vaccine strains are less effective at cross-neutralising current circulating field strains isolated from sick cats, but these findings are controversial and further independent studies will be required to investigate vaccine efficacy against different FCV strains. Nevertheless, it is generally recommended that all healthy cats should be vaccinated against FCV, since vaccination provides good protection against acute oral and upper respiratory tract disease in the majority of cats. However, sterilising immunity is not induced, and so vaccinated cats can still become infected and subsequently shed FCV. It is important to consider that current vaccines are not able to protect cats equally well against all the currently circulating field strains of FCV.

Feline Leukemia and Sarcoma Viruses (*Retroviridae*)

Brian J Willett and Margaret J Hosie, MRC-University of Glasgow Centre for Virus Research, Glasgow, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

This is an update of J.C. Neil, Feline Leukemia and Sarcoma Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00397-6.

History

In the early 1960s, Harry Pfaff, a veterinary practitioner in the Glasgow area, observed a cluster of lymphoma cases in a local multi-cat household. Suspecting a possible infectious etiology, he contacted Professor William Jarrett, a veterinary pathologist at the University of Glasgow. Using electron microscopy, Professor Jarrett and his colleagues visualized virus-like particles in tumor material from the cats, and demonstrated that these particles bore a striking resemblance to the virus associated with murine leukemia, reporting their findings in *Nature* in 1964. Subsequent studies demonstrated that these feline leukemia viruses (FeLVs) could be transmitted to cats where they induced lymphosarcomas and a range of degenerative diseases, including anemias and thymic atrophy.

Following these studies, Snyder and Theilen isolated a retrovirus from a feline fibrosarcoma that rapidly reproduced this tumor on inoculation into experimental cats. It is now recognized that feline sarcoma viruses (FeSVs) arise by recombination between FeLV and cellular proto-oncogenes and that, in contrast to FeLV, these viruses are not transmitted from cat to cat.

FeLV remains an important virus clinically, affecting both domestic cats and wild felids. Several highly efficacious FeLV vaccines are available and are used widely. This, in conjunction with reliable testing and control programmes, has led to a significant decline in the prevalence of FeLV infection (<2%) across Europe and North America. Prevalence remains high in some areas, for example N.W. China (~11%) and Thailand (~25%).

As a naturally occurring disease in an outbred host, FeLV has served as a paradigm for the natural history and molecular pathogenesis of the gammaretrovirus subfamily. It also played a foundational role in cancer genetics as a transducing agent which led to the discovery of novel cellular transforming genes.

Taxonomy and Classification

FeLVs are RNA viruses and belong to the family *Retroviridae*. They are further classified in the genus *Gammaretroviruses*.

Virion and Genome Structure

The virion particles are around 100 nm in diameter and consist of an outer membrane derived from the host cell surrounding a spherical core particle. The core encapsidates the viral genome which, as in other members of this viral family, is present as two linear single-stranded RNA molecules linked as a dimer. The virion RNA is positive-stranded and resembles cellular RNA having a 5' cap and a 3' poly(A) tract. As deduced from sequencing of proviral forms, the FeLV genome is around 8 kb long with a 67 base terminal redundancy and the gene order *gag-pol-env*.

The particles have surface spikes composed of multimers of the two *env*-coded proteins, the gp70 surface glycoprotein (SU), and the p15E transmembrane anchor protein (TM). Inside the envelope are the structural *gag* gene products which form a spherical core particle composed of p27, the major capsid protein (CA), with an outer layer formed by the p15 matrix protein (MA). Another *gag* product, the p10 nucleocapsid (NC), is associated with the virion RNA. Other minor virion proteins encoded by the *pol* gene comprise the protease (PR), reverse transcriptase (RT), and integrase (IN) enzymes.

Replication

Following attachment to specific host cell-surface receptors and fusion of the viral envelope with the cellular membrane, the viral core is internalized into the cytoplasm of the cell. Uncoating is followed by reverse transcription in which the virion RNA is converted into a double-stranded DNA form by the virion RT which uses a proline tRNA primer and carries a ribonuclease H function that degrades the virion RNA. After nuclear translocation, viral integration is catalyzed by the IN protein and involves the creation of a staggered cut in cellular DNA with a consequent 4 bp duplication of host DNA at the insertion site.

The proviral form of FeLV is flanked by long terminal repeats (LTRs) of 480–560 bp. These are generated during reverse transcription by duplication of unique sequences at the 3' (U3) and 5' (U5) ends of the RNA genome. The LTRs contain promoters and enhancers that drive transcription of viral RNA and also processing signals for cleavage and polyadenylation of the RNA transcripts. The 5' LTR functions to initiate transcription while the 3' LTR acts primarily as an RNA processing signal.

The virion RNA can function as a messenger RNA for Gag and Pol products, while a spliced subgenomic mRNA of around 3 kb encodes the Env products. Most full-length RNA translation products terminate at the 3' end of *gag* to produce the Pr65gag precursor, while a small percentage read through into *pol* by misreading of a UAG termination codon, generating the Pr180Gag-pol precursor. During and after the budding process, the virion aspartyl PR catalyzes the cleavage of both precursor proteins to their mature forms. The envelope gene products are synthesized as a Pr80env precursor and processed by cellular PRs to the mature, disulfide-linked gp70 and p15E envelope proteins. The *gag* gene is also abundantly expressed in an alternative, glycosylated form *via* an upstream AUG codon. This product is expressed on the cell surface and shed after cleavage by cellular PRs. It is dispensable for *in vitro* virus replication but is highly conserved and may play a role *in vivo*, for example in counteracting intrinsic immune activity as has been described for the equivalent gene product in murine leukemia virus.

Assembly of virus particles occurs at the cell surface by extrusion of cores which form at the budding site, concomitantly acquiring a host cell-derived outer membrane with virus-coded surface spikes. Virus replication and release is often noncytopathic.

Geographic Distribution

FeLV occurs worldwide in domestic cat populations, although prevalence varies significantly and has declined in pet cats in areas where reliable testing, vaccination and control have been instigated. FeLV has also been isolated from several wild felids, including the European wild cat (*Felis silvestris*), Florida panther (*Puma concolor coryi*), Iberian lynx (*Lynx pardinus*) and Jaguar (*Panthera onca*). Endogenous retroviral sequences closely matched to FeLV are found in the sand cat (*Felis margarita*) and the jungle cat (*Felis chaus*). Although not a direct source of disease, these endogenous sequences may potentially participate in recombination with exogenous FeLV to generate variant viruses with altered host range.

Epidemiology

The outcomes of FeLV infection fall into several categories, which vary in likelihood according to the age and immune status of the exposed host. The majority of cats undergo a transient infection lasting up to 3 months, during which they are viremic and shed virus. They then develop neutralizing antibody and concomitantly clear infectious virus and, a little later, virus antigen from the blood stream. Some cats appear to clear virus infection successfully, while others may harbor latent virus in the bone marrow for some years. A recent study based on analysis of virus loads by polymerase chain reaction (PCR) suggests that animals that control viremia may be further subdivided into either abortive, or regressive, sometimes known as latent, infection. Even where latent infection persists, reactivation is not a frequent event and the vast majority of these cats do not develop an FeLV-related disease. However, at this stage virus can be reactivated by immunosuppression. The final group (persistent or progressive infection) remains actively infected, shedding virus from epithelial surfaces and displaying high titer plasma viremia. Such cats may remain apparently healthy for 2–3 years before succumbing to an FeLV-related disease.

The proportion of cases falling into these groups differs between multi-cat households and those households containing one or two free-ranging cats. In the former case, the introduction of an FeLV carrier results in repeated exposure of susceptible cats, often at a young age so that up to 30%–40% become persistently viremic and at risk of disease. Approximately 50% of free-ranging urban and suburban cats have serological evidence of exposure to FeLV but only 1%–5% of these cats are actively infected and the disease incidence is correspondingly lower.

Dual infection with FeLV and feline immunodeficiency virus (FIV) occurs and is associated with rapid disease onset, particularly if cats with preexisting FeLV infection encounter FIV. Rapid death of dually infected animals may reduce the apparent overlap of these agents in the field, but the populations at risk of infection also differ. FIV infection rates increase directly with age while persistent FeLV infection has a peak incidence in young cats.

FeLV Subgroups and Host Range

FeLV isolates were initially classified into three subgroups; A, B, C according to their viral interference properties in feline fibroblast cells *in vitro*. Viruses of a given subgroup prevent superinfection (interfere) with other viruses of the same subgroup (Table 1). This property is based on the use of three different host cell-surface receptors by FeLV-A, B, and C, and the blockade and/or down-modulation of these receptors in persistently infected cells by viral Env glycoproteins. Primary receptors for subgroups A, B, and C have been identified and shown to be transmembrane transporter molecules which the virus has subverted to gain entry to the host cell (Table 1). Subsequent studies have identified additional, less frequent viral variants with distinct interference properties and receptor usages, although the contributions of such viral variants to the pathogenesis of disease in the wider cat population remains unclear. The generation of novel variants occurs by either mutation or recombination. During the process of mutation, viruses may emerge with an intermediate phenotype, for example isolate FY981 can use either the FeLV-A or C receptors for infection. Notable variants include FeLV-T, a “lymotropic” variant with complex entry requirements. FeLV-T does not replicate well in fibroblast cells and appears to use the FeLV-A receptor in conjunction with an auxiliary mechanism in which a truncated *env* gene product encoded by endogenous FeLV sequences (FeLIX) is used as a co-receptor through binding to the FeLV-B receptor.

Table 1 Properties of feline leukemia virus subgroups

Subgroup	Origin	Receptor	Function	Pathogenesis
A	Exogenous	feTHTR1	Thiamine transport	Minimally pathogenic to acute immunosuppression
B	Recombination FeLV-A × endogenous FeLV	Pit-1 (Pit-2)	Phosphate transport	More common in leukemic cats Some isolate-specific diseases, <i>e.g.</i> , FeLV-GM1 myeloid leukemia
C	Mutation of FeLV-A (Env vrA)	FLVCR1 (FLVCR2)	Heme export	Erythroid hypoplasia
D	Recombination FeLV-A × endogenous retrovirus ERV-DC	Unknown	Unknown	Unknown
T	Mutation of FeLV-A (outside RBD)	FeLV-A receptor + FeLIX, Pit-1		Acute immunosuppression
TG35-2	Mutation of FeLV-A (Env vrA)	feRFC	Reduced folate transport	Unknown

FeLV-D is formed by recombination between exogenous FeLV and the endogenous cat retrovirus ERV-DC. FeLV-D appears to use a distinct receptor to the A, B and C subgroups. FeLV-TG35-2 is a virus isolated from a single cat in Japan and uses the feline reduced folate carrier as an entry receptor.

Natural isolates contain either subgroup A alone, or mixtures of subgroups A + B, A + C, or A + B + C. FeLV isolates of subgroup A have a limited tropism in cell culture due to their use of the receptor THTR1 (*e.g.*, FEA and HEK293 cells), whereas subgroup B and C isolates have a greatly expanded host range due to their use of Pit-1 and FLVCR1 respectively, infecting cell lines from diverse species, including cat, human, mink, and canine cells. FeLV infection is generally noncytopathic and persistent and the virus is commonly propagated in long-term cultures of embryo-derived fibroblasts. Some strains such as FeLV-T or FeLV-C are cytopathic or induce apoptosis in cells of lymphoid origin *in vitro*, reflecting their *in vivo* pathogenic properties.

Clinical Features and Pathology

Of those cats that become persistently viremic following FeLV exposure, over 80% die within 3.5 years. Most young cats infected with FeLV die from degenerative diseases rather than from tumors. Profound immunosuppression associated with thymic atrophy is a common finding in kittens. Other diseases seen in FeLV-infected cats include enteritis, immune complex glomerulonephritis, pancytopenia, and hemolytic anemia. Erythroid hypoplasia, an acute disease involving failure of red cell development past the burst-forming unit (BFU) stage, is specifically associated with FeLV subgroup C.

The most common neoplasm induced by FeLV is lymphosarcoma of T-cell origin, usually restricted to the thymus or sometimes occurring as a multicentric tumor in lymph nodes. The tumors often develop between 1 and 3 years after infection and the first signs may be chronic wasting and anemia. At presentation, the normal architecture of the lymphoid organ has usually been destroyed by a monomorphic infiltrate of lymphoblastic cells. The thymic tumors frequently display a rearrangement of the T-cell antigen receptor β -chain gene and may also express the co-receptor molecules CD4 and/or CD8. FeLV is also commonly associated with myeloid leukemias and a myelodysplastic syndrome-like disease, as well as with other forms of hematopoietic malignancy. Multicentric fibrosarcoma is a rare sequel to FeLV infection but these tumors are often associated with the *de novo* generation of a FeSV. FeLV is also found in association with 35% of alimentary tumors, primarily of B cell origin, but the virus is not always clonally integrated in these tumors and the role of the virus is, therefore, unclear. FIV can also increase the frequency of malignant diseases in cats, and some rare cases arise on a background of dual infection.

Envelope Gene Variation and Pathogenicity

The common infectious form of FeLV is FeLV-A which is a remarkably highly conserved virus as shown by sequence analysis of several strains and serotypic analysis of a much larger number. FeLV variants frequently arise from FeLV-A by mutation and recombination, and such variants are often implicated in the acute diseases that develop in persistently infected cats. The variant viruses generated from FeLV-A are generally dependent on the continued presence of the prototype for their propagation *in vivo*. However, as the variants are transmitted less efficiently and are in some cases rapidly fatal, they tend to die out with the host while the prototype FeLV-A continues to colonize new hosts (Fig. 1).

The most commonly isolated FeLV recombinants are subgroup B viruses (Table 1). These are derived by recombination between FeLV-A and endogenous FeLV-related proviruses which are found in the genome of the domestic cat and related small feline species. Although the endogenous FeLV-related proviruses all appear to be replication defective, their envelope genes can be rescued by the recombination process leading to the generation of FeLV-B viruses. FeLV-B can infect cells refractory to, or already containing, FeLV-A by virtue of their distinctive receptor specificity.

Fig. 1 Life cycle of FeLV in its natural host, the domestic cat. FeLV-A is the most readily transmitted form and is found in 100% of isolates. In cats which become persistently viremic (progressive infection), the virus may evolve by recombination or point mutations to generate pathogenic variants that can lead to the rapid demise of the infected host animal. Multiple variants can arise in a single host. Few of these variants show any capacity for horizontal transmission to new hosts with the exception of FeLV-B. In this way, FeLV inflicts a substantial disease burden without significantly reducing host numbers.

Table 2a FeLV gene transduction in neoplasia

Gene	Normal function of host gene product	Associated tumor	Examples ^a
<i>abl</i>	Plasmamembrane protein kinase	Fibrosarcoma	FeSV-HZ2
<i>fes</i>	Plasmamembrane protein kinase	Fibrosarcoma	FeSV-GA, -HZ1, -ST
<i>fgr</i>	Plasmamembrane protein kinase	Fibrosarcoma	FeLV-GR, -TP1
<i>fms</i>	Receptor protein kinase (CSF-1 receptor)	Fibrosarcoma	FeSV-SM, -HZ5
<i>kit</i>	Receptor protein kinase (SCF receptor)	Fibrosarcoma	FeSV-HZ4
<i>myc</i>	Transcription factor	T-cell lymphoma	FeLV (T3, T17, FTT)
<i>Notch2</i>	Transmembrane receptor	T-cell lymphoma	(Inoculum FeLV-61E) ^a
<i>sis</i>	Growth factor (B chain PDGF)	Fibrosarcoma	FeSV-PI
<i>trc</i>	T-cell antigen receptor (β -chain)	T-cell lymphoma	FeLV-T17

^aIsolated from naturally occurring tumors apart from the indicated exception.

The anemia-inducing FeLV-C isolates are rarer and appear to be derived from FeLV-A by mutation of a single variable domain (VRA) of the *env* gene. The acute disease properties of these variants appear to be due to compromised viability of erythroid progenitor cells due to perturbation of the FeLV-C receptor, a vital heme exporter.

Minor *env* mutations also appear to give rise to the acutely immunosuppressive FeLV-FAIDS variants. The prevalence of acutely immunosuppressive viruses in nature is unknown, but immunosuppressive disease is a common manifestation of FeLV infection.

The relationship of subgroup variation to oncogenesis is complex. FeLV-B recombinants are more common in tumor-bearing than in healthy infected cats. This higher frequency might reflect merely longer-standing infection, but some FeLV-B-containing isolates have an altered spectrum of neoplastic disease. For example, FeLV-GM1, which contains a replication-defective FeLV-B component, induces mainly myeloid leukemia.

FeLV Oncogenesis: Virus Evolution and Mutagenesis of Cellular Oncogenes

Two modes of virus-induced host gene mutation have been described in FeLV-associated cancers. The first is 'transduction', where recombination leads to the generation of an acutely oncogenic variant in which viral gene sequences are replaced by a host-derived insert. Such viruses are replication defective and are found in nature in association with a replication-competent FeLV helper virus.

Multicentric fibrosarcomas of young cats are relatively rare, but are generally FeLV positive and frequently involve a novel sarcoma virus. Similarly, transduction of *c-myc* has been observed in up to 20% of naturally occurring thymic lymphosarcomas in FeLV positive cats. In all, nine different host cell genes have been shown to be transduced by FeLV (Table 2a). The transducing viruses induce tumors with short latency in cats and in the case of FeSVs may transform cells in tissue culture.

Table 2b Insertional mutagenesis and FeLV oncogenesis

<i>Common integration site</i>	<i>Gene function</i>	<i>Tumor</i>
<i>fit-1</i>	Transcription factor (<i>c-myc</i>)	T-cell lymphoma
<i>flvi-1</i>	Unknown	non-T, non-B lymphoma
<i>flvi-2 (bmi-1)</i>	Transcription factor	T-cell lymphoma
<i>c-myc</i>	Transcription factor	T-cell lymphoma
<i>pim-1</i>	Protein kinase	T-cell lymphoma
<i>flit-1</i>	Growth factor receptor?	T cell lymphoma

Alternatively, host genes can be affected by proviral 'insertional mutagenesis' (*cis*-activation). Four known oncogenes and two uncharacterized novel integration loci have been identified as common tumor-specific insertion sites for FeLV in thymic lymphosarcomas (Table 2b). In this respect FeLV oncogenesis appears remarkably similar to that of the murine gammaretroviruses.

Changes within the LTR are also a feature of tumor-associated FeLV. In thymic lymphosarcomas, sequence duplications of the core enhancer domain are found frequently and have been shown to arise *de novo* from infection with molecularly cloned FeLV isolates lacking such features. By analogy with the murine oncoretroviruses, the duplications are likely to increase the oncogenicity of the virus and reduce the latent period for tumor formation, possibly by increasing the potency of viral enhancer activity on nearby cellular promoters. There is evidence that these adaptive changes to the LTR operate tissue-specifically and proviruses carrying different duplications of LTR regions 5' and 3' to the core-enhancer region have been identified in myeloid leukemias and non-T, non-B splenic lymphomas, respectively. Chimeric murine retroviruses carrying the FeLV enhancer region have been generated, confirming that the tissue specificity is carried by this structure.

Immune Response

Unlike infection with the lentiviruses HIV and FIV, FeLV infection of cats can lead to recovery. There is evidence that both neutralizing antibodies and virus-specific cytotoxic T cells (CTLs) play a role in resistance as either can be used to prevent or limit infection by passive transfer. In natural infection, CTLs to virus structural protein epitopes can be detected as early as 1 week after infection. In contrast, neutralizing antibodies may not be detected until approximately 6 weeks post infection.

In the early literature on FeLV, a distinction was made between antiviral immunity and antitumor immunity. Cats with antitumor (FOCMA) antibody were thought to be protected from tumor development. This antibody response is now believed to be directed to endogenous FeLV *env* proteins and its role in modulating tumor development is uncertain.

Transmission

Cats persistently infected with FeLV shed virus in their saliva, urine, and feces but, as the virus is fragile, close contact is required for transmission. The most frequent routes involve saliva and transplacental spread. Kittens infected *in utero* become persistently infected, but the consequences of infection in older cats depend on a number of factors. There is an age-related resistance to infection such that cats up to 12 weeks of age are highly susceptible, but above 16 weeks they are difficult to infect either naturally or experimentally.

FeLV subgroup A is always found in field isolates while approximately half also contain FeLV-B, whereas FeLV-C is present in only 1%–2% of isolates. Although FeLV-B can arise *de novo* by recombination, it can also be transmitted between cats. This occurrence is dependent on pseudotype formation in which the genome of the B virus becomes enclosed in an envelope containing glycoproteins of the A subgroup.

Prevention and Control

Successful control measures can be adopted in multi-cat households by removing or isolating persistently infected animals. Productively infected cats are identified routinely by the detection of soluble FeLV antigen (p27) by ELISA or immunomigration test, proviral DNA PCR on whole blood, RT-PCR for viral RNA in blood or saliva, or less frequently by direct virus isolation in culture. A few cats remain persistently antigenemic but nonviremic. These cats do not usually transmit the virus unless they are shedding virus in the milk or saliva.

Numerous vaccine strategies have been shown to confer protection against FeLV under laboratory conditions and FeLV was the first retrovirus for which commercial vaccines were developed. Vaccines in current use include whole inactivated virus preparations, subunit vaccines comprising recombinant viral Env protein expressed in bacterial cells, and a canarypox recombinant virus

expressing Gag and Env. These vaccines offer significant protection against experimental challenge and are under evaluation for longer-term efficacy in the field. These vaccines do not generate sterilizing immunity but appear to prime the immune system to favor clearance of virus infection instead of persistent viremia.

Future Perspectives

There is continuing interest in control of FeLV infection due to its importance in veterinary medicine. In the future we can look forward to improvements in vaccine efficacy and further dissection of the host responses that confer protection. While the focus of attention of cancer genetics has moved on to more easily manipulated models, FeLV remains as a useful touchstone for our understanding of retroviral pathogenesis in an outbred, naturally infected host.

Glossary

Alloherpesvirus Herpesvirus classified in the family *Alloherpesviridae*, order *Herpesvirales*, grouping all herpesviruses infecting fish and amphibians described until now.

Bacterial artificial chromosome Large DNA vector that can allow the stable maintenance and efficient mutagenesis of herpesvirus genome in *Escherichia coli*, followed by the reconstitution of progeny virions after its transfection into permissive eukaryotic cells.

Behavioral fever Phenomenon by which ectotherms increase their body temperature by moving to warmer places in response to an infection.

Ectotherm Organism unable to internally self-regulate its body temperature, therefore relying on external sources of heat.

Hyperplastic lesion Increase of the size of a tissue or organ as a result of cell proliferation.

Latency Maintenance of viral genome as a non-integrated episome associated with minimal viral protein expression and absence of infectious particle production.

Viral reactivation Phenomenon by which the state of viral infection switches back from latency to productive infection.

Introduction and Classification

Herpesviruses form a diverse group of viruses initially described by a conserved virion structure containing a large, linear double-stranded DNA (dsDNA) genome. Indeed, the unifying property of herpesviruses is virion morphology rather than genetic content. Herpesviruses are now classified in the order *Herpesvirales* and share only one convincing conserved gene, i.e., the ATPase subunit of the terminase. Phylogenetic analysis of this gene has led to the current classification of herpesviruses by the International Committee on Taxonomy of Viruses (ICTV). The order *Herpesvirales* is now composed of three viral families, namely the families *Herpesviridae*, *Alloherpesviridae* and *Malacoherpesviridae*. Until now, herpesviruses of amniotes (reptiles, birds and mammals) have been grouped in the family *Herpesviridae*. Herpesviruses of molluscs are encompassed within the family *Malacoherpesviridae*. Finally, herpesviruses of fish and amphibians are classified in the family *Alloherpesviridae*.

The family *Alloherpesviridae* contains four genera with 13 virus species currently accepted by the ICTV (Table 1). The alloherpesviruses of amphibians (*Ranid herpesvirus* 1; 2 and 3 [RaHV]) belong to the genus *Batrachovirus*, while fish alloherpesviruses have been clustered into three genera. The genus *Cyprinivirus* comprises the alloherpesviruses of cyprinids (*Cyprinid herpesvirus* 1; 2 and 3 [CyHV]) and that of eel (*Anguillid herpesvirus* 1 [AngHV]). The genus *Ictalurivirus* includes the alloherpesviruses isolated from catfish (*Ictalurid herpesvirus* 1 and 2 [IchV]) and sturgeon species (*Acipenserid herpesvirus* 2 [AcHV]), while the genus *Salmonivirus* consists of herpesviruses of salmonids (*Salmonid herpesvirus* 1; 2 and 3 [SalHV]) (Fig. 1(A)). Interestingly, viruses of the genera *Cyprinivirus* and *Ictalurivirus* are able to infect fish from two different superorders (Elopomorpha, Ostariophysi) or subclasses (Chondrostei, Neopterygii), respectively. This observation supports a more recent evolution of the family *Alloherpesviridae*, associated with a lesser degree of coevolution of some alloherpesviruses with their hosts. In addition to the accepted viral species, more than 10 putative alloherpesviruses were detected by PCR from a wide range of fish species (Table 1). Unfortunately, only partial genome sequences are available. The official taxonomical classification of these viruses is still pending. However, according to phylogenetic analyses, these viruses undoubtedly belong to the family *Alloherpesviridae*. Some of them clearly cluster into already existing genera (Fig. 1(B)), e.g., SalHV-4 and SalHV-5 are likely going to expand the genus *Salmonivirus*. Other viruses (e.g., AcHV-1; EsHV-1) cannot be grouped with viruses of any existing genera (Fig. 1(B)). Further genomic data are needed from these virus species in order to establish their evolution and taxonomic classification. The

Table 1 Classification of fish and amphibian alloherpesviruses according to the ICTV (Order *Herpesvirales*, Family *Alloherpesviridae*)

Genus	Viral species (ICTV list)	Viral name	Viral acronym	Alternative viral name (s)	Susceptible host (s)
<i>Batrachovirus</i>	<i>Ranid herpesvirus 1</i> ^a	Ranid herpesvirus 1	RaHV-1	Lucké tumor herpesvirus	Northern leopard frog (<i>Lithobates pipiens</i>), green frog (<i>L. clamitans</i>), pickerel frog (<i>L. palustris</i>)

	N/A	Silurid herpesvirus 1	SiHV-1		Glass catfish (<i>Kryptopterus bicirrhus</i>)

^aDesignates the type species of each genus (ICTV, 2018).

complexity and precision of the current classification are likely to rapidly evolve in the future based on the description of new alloherpesvirus members. Finally, many fish species have experienced integration of alloherpesvirus sequences fused with transposons into their genomes.

Virion Structure

In terms of virion structure, alloherpesviruses are no exception to the remarkably conserved and morphologically distinct architecture found throughout the *Herpesvirales* order. It was demonstrated, for example, that the nucleocapsid of IchHV-1 was strikingly similar to that of human herpesvirus 1 (HHV-1 also known as herpesvirus simplex 1). The structure of herpesviruses is, from the center outwards, as follows: (i) a densely packed genome consisting of a single copy of linear dsDNA encapsulated in an icosahedral nucleocapsid ($T = 16$) with a diameter of 100–130 nm; (ii) an amorphous proteinaceous tegument layer; and (iii) a lipid bilayer envelope acquired from the host and bearing various viral glycoproteins.

Genome

Until now, 11 complete alloherpesvirus genomes have been sequenced and partial genome sequences are available from 11 more viruses. The full-length genomes of SiHV-1 (potential ictalurivirus) and BfHV-1 (potential batrachovirus) were released recently.

Fig. 1 Phylogenetic tree of the family *Alloherpesviridae*. The analyses were based on the Bayesian analysis (WAG amino acid model) of the deduced amino acid sequences of DNA polymerase genes (134 and 113 amino acid residues, respectively for panel A and B). High statistical values confirm the topology of the trees. The four main genera within the family *Alloherpesviridae* are designated by different colored lines on the trees. Panel A: phylogenetic tree of the classified viral species in the *Alloherpesviridae* family. Panel B: phylogenetic tree of the classified and unclassified potential members of the *Alloherpesviridae* family. AciHV: acipenserid herpesvirus; AngHV: anguillid herpesvirus; BfHV: bufonid herpesvirus; CyHV: cyprinid herpesvirus; EsHV: esocid herpesvirus; GaHV: gadid herpesvirus; IchiHV: ictalurid herpesvirus; PeHV: percid herpesvirus; RaHV: ranid herpesvirus; SalHV: salmonid herpesvirus; SiHV: silurid herpesvirus. ^aPredicted to encode functional proteins. Includes ORFs duplicated in TR.^bDesignates Reference Sequences (RefSeq) in the GenBank.

Note: U: Unique region; TR: Terminal repeat; kbp: kilobase pair.

The genome size of alloherpesviruses range between 134 and 295 kilobase pairs (kbp) containing 90–186 Open Reading Frames (ORFs). There are significant differences in the genome size of viruses belonging to different genera. The (potential) ictalviruses have the smallest genomes ranging from 134 to 149 kbp, while the estimated genome size of salmoniviruses is around 170 kbp. The genomes of the (potential) batrachoviruses are comprised within the range 158–232 kbp, and the largest genomes are presented by cypriniviruses ranging from 245 to 295 kbp (Table 2). The genome of CyHV-3 is the largest of all herpesviruses sequenced so far. The structure of alloherpesvirus genomes is simpler than that of most of the *Herpesviridae*. Most of their genomes contain only one unique region which is flanked by direct terminal repeats (TR). On the contrary, several of the members of the *Herpesviridae* family are more complex and composed of one long region associated with one or sometimes two short unique regions flanked by internal and terminal repeats. Fish alloherpesviruses have long TR, while frog herpesviruses have very short or even no detectable TR (Table 2). Alloherpesviruses differ from the members of the *Herpesviridae* family in the number of conserved genes. The latter have a subset of about 40 convincingly conserved genes in members of the family *Herpesviridae*. While alloherpesvirus genomes share 40–60 homologous genes within a genus, there are only 12 genes which have homologs in all completely sequenced alloherpesvirus genomes. These encode major structural proteins and enzymes involved in replication and packaging of viral DNA into virions.

Life Cycle

Infection begins with viral entry, where surface glycoproteins attach to cellular receptors, leading to cell penetration. Two non-exclusive mechanisms of viral penetration have been described in the *Herpesviridae* family, i.e., direct fusion with the plasma membrane, or endocytosis followed by fusion of the viral envelope with the endosome membrane, both resulting in the release of the nucleocapsid, coated by tegument proteins, into the cytoplasm (Fig. 2). Nevertheless, the entry mechanisms of alloherpesviruses are still poorly known. Retrograde transport ensues along microtubules to the nuclear pores, where the viral linear genome is delivered into the nucleus. After circularization of the genome, cellular transcription machinery is used for expression of viral genes as a cascade, starting with immediate early genes, followed by early and late categories. As a result of early gene expression, replication of virus DNA is mediated by viral DNA polymerase, leading to the synthesis of branching concatemers. Finally, late gene expression results in the generation of structural proteins that assemble in the nucleus as capsids. Concatemers are then cleaved before the viral genomes are loaded into capsids. Nuclear egress begins with primary envelopment whereby budding at the inner nuclear membrane occurs, with release into the perinuclear space. From there, nucleocapsids exit the nucleus by fusion of the primary envelope with the outer nuclear membrane (de-envelopment). Naked capsids then get to sites of virion assembly and bud into vesicles belonging to the *trans*-Golgi network, where tegument addition and secondary envelopment with acquisition of the glycoprotein-studded envelope arise. Lastly, enveloped virions undergo egress via exocytosis.

Increasing evidence points to alloherpesviruses displaying the capacity, as found in the *Herpesviridae* family, to establish latent infections. The balance between productive and latent infection is intricately linked to host biology, as latency may be interrupted by reactivation that reverts to a productive infection. In alloherpesviruses, water temperature could be a key factor in switching between productive and latent infections.

Epidemiology

Fish Alloherpesviruses

Alloherpesviruses share the general tendency of herpesviruses to possess a narrow host range, although limited infection can sometimes occur in non-natural host species. For example, CyHV-1 is usually restricted to common carp but was detected in

Fig. 2 Schematic representation of herpesvirus productive life cycle. Schematic representation and electron microscopy examination of CyHV-3 virion (upper left panel, bar represents 100 nm). Typical replication cycle of herpesviruses. Diagrammatic representation of the herpesvirus replication cycle, including virus entry and dissociation of the tegument, transport of incoming capsids to the nuclear pore, and release of viral DNA into the nucleus. Capsid assembly, DNA packaging, primary, secondary envelopment and egress are also illustrated. MTOC: Microtubule Organizing Center; ER: Endoplasmic Reticulum. golden ide (*Leuciscus idus*) imported from Germany into North America. For CyHV-3, multiple vertebrate and invertebrate species have been identified as bearing viral DNA and being a potential epidemiological risk factor of viral spreading.

The geographical distribution of alloherpesviruses is variable: for instance, whereas members of the *Cyprinivirus* genus are found worldwide, others have only been associated with restricted geographical areas and contexts. Such is the case for IchV-2 that caused mass mortalities in black bullhead catfish farms in Italy in the late 1990s. In the case of CyHV-3, the first outbreaks in 1997 in Germany and its rapid worldwide distribution were attributed to international trade of common and koi carp and notably the methods used in koi carp competitions before awareness of this pathogen was commonplace. It can therefore be stated that the epidemiology of some alloherpesviruses is tightly interwoven with the precise use and trade of the domesticated host species.

Deadly outbreaks of CyHV-3 have occurred in many natural habitats such as in some North American lakes, but have not caused any long-term decrease of common carp populations. Recently, the high virulence of CyHV-3 associated with its believed absence in Australia has led to the hypothesis of using this virus to control common carp populations which are considered as an invasive species in this country. However, the predicted safety and efficacy of this method have recently been under important scientific debate.

Amphibian Alloherpesviruses

The real causes of alloherpesvirus emergence and spread in free-ranging amphibians are mostly unknown. However, the impact of human activities on their habitat and the climate may play a relevant role. Of the known batrachoviruses, RaHV-1 has been detected in free-ranging leopard frogs (*Lithobates pipiens*) in specific areas of the North American continent where, to the best of our knowledge, it has remained confined. The prevalence of RaHV-1 associated tumors ranged between 1% and 9% according to the collection site. A drastic reduction of the infected populations of leopard frogs was recorded in the 70's. Currently, no information is available concerning possible reemergence of the virus. Differently, RaHV-3 and BfHV-1 have been recorded in Europe only, in the common frog (*Rana temporaria*) and common toad (*Bufo bufo*), respectively. Their actual and current significance in the context of amphibian disease ecology is currently unknown.

Pathogenesis

Fish Alloherpesviruses

Fish alloherpesviruses are characterized by their temperature dependency, a consequence of the ectothermic nature of their hosts. The optimal temperature for viral replication and disease is variable among alloherpesviruses. Whereas AngHV-1 infection is

promoted by high temperatures (25°C), SalHV-3 outbreaks are reported when temperatures are low (8–10°C). In natural conditions, if the environmental water temperature is suboptimal for virus replication, the induced disease will be less severe or even asymptomatic, explaining the seasonal occurrence of alloherpesvirus diseases. Interestingly, expression of behavioral fever was described in common carp infected by CyHV-3.

Studies of CyHV-3 pathogenesis mimicking natural conditions demonstrated that the skin is the major portal of entry of the virus after inoculation of carp by immersion, whereas the virus would penetrate through the pharyngeal periodontal mucosa following oral contamination. Viral spreading within the infected host is probably promoted by infected white blood cells allowing rapid spread in almost all tissues soon after inoculation.

Horizontal transmission of fish alloherpesviruses can occur either directly between fish or indirectly, through several potential vectors (e.g., water, fish droppings). Salmoniviruses were detected in ovarian fluids, suggesting a possible vertical transmission. Vertical transmission was demonstrated for IchV-1 after detecting the virus in offspring from IchV-1 positive broodstocks.

The hallmark of herpesviruses is their ability to establish latency in their host after initial productive infection. Some evidence of latency has been described for CyHV-1, CyHV-3, AngHV-1, SalHV-2 and IchV-1 fish alloherpesviruses. The latency of alloherpesviruses in fish surviving the primary infection allows viral transmission to naïve fish upon disease reactivation. This aspect of the virus biology results in a certain spatial and temporal flexibility for viral maintenance in the host population.

Amphibian Alloherpesviruses

Pathogenesis of the *Batrachovirus* associated disease is virtually unknown. RaHV-1 has been shown to be the etiologic agent of Lucké's adenocarcinoma in leopard frogs. However, it is not known how the virus induces tumor development although environmental temperature may play a role. The disease could be reproduced by only infecting frogs during their larval stage with tumor extract. Viral replication appears to be dependent on low environmental temperatures, whereas tumor growth and metastasis would be promoted at higher temperatures. Regarding temperature and seasonality, the proliferative dermatitis associated with RaHV-3 and BfHV-1 are observed right after hibernation, during the mating season, between the end of winter and beginning of spring, when the environmental temperature is low. No virus-associated lesion has been reported during the later spring and summer. The molecular bases of the associated diseases are not known and Koch's postulates have not been fulfilled for these two viruses.

Clinical Features

Fish Alloherpesviruses

Clinical aspects induced by fish alloherpesviruses can vary substantially among outbreaks or individuals. Indeed, variations are observed in the severity of clinical signs according to diverse factors including, but not restricted to, those related to the environment (temperature, density of the population) and host (age of the individuals, genetics, immune status). Primary infection involves productive viral replication that may result in viremia and acute disease associated with high morbidity and mortality. In general, fish exhibit non-specific behavioral changes including lethargy, hyperexcitability, erratic swimming or gasping at the water surface. Diseases associated with infection of naïve individuals by alloherpesviruses can include epithelial lesions, diffuse multisystemic hemorrhages, ascites, kidney and liver necrosis (Fig. 3(A), Table 3).

Contrarily to their *Herpesviridae* family counterparts, alloherpesviruses usually induce severe diseases in their hosts. This may result from a milder degree of coevolution with their respective hosts. Alloherpesvirus infections might nevertheless be artificially enhanced by aquaculture methods. Among the most important fish alloherpesviruses, CyHV-2, CyHV-3 and IchV-1 cause a systemic and lethal disease (Fig. 3(A); Table 3) characterized by mass outbreaks associated with high mortalities. During the summer, when temperature is optimal for the occurrence of IchV-1 disease, 90% of fry and fingerlings may die in less than two weeks. During CyHV-3 infection, infected individuals may begin to die at 6–8 days post infection. Mortality rates are in general up to 70%–80% of infected individuals but they can reach 100% in some cases. Mass mortalities within 24 h were also recorded in CyHV-2 infected gibel carp. CyHV-1, IchV-2, AciHV-2, SalHV-2 and SalHV-3 primary infections can also induce lethal diseases.

Development of a benign epithelial hyperplasia, also called herpetic lesion or papilloma is another clinical pattern largely observed in alloherpesvirus infections. This clinical feature can be observed during primary productive infection with AciHV-2, SalHV-3 and SalHV-4 (Fig. 3(B)). In addition, this lesion can arise during recrudescence of a previous infection. Indeed, while CyHV-1 and SalHV-2 primary infection is typically characterized by an acute systemic disease, the recrudescence of the disease in survivors is associated with epithelial tumors. Papillomas associated with CyHV-1 infection appear 5–6 months after primary exposure in most survivors and are more commonly observed on the skin (body, fins, mouth) and at the site of intraperitoneal inoculation. Similarly, epitheliomas in SalHV-2 disease are observed around the mouth, at the caudal fin, operculum, and the body surface. These lesions may persist for one year. Experimental challenges show that tumor occurrence varies between species (12%, 40%–60%, and 100% in rainbow trout, chum salmon and masu salmon, respectively).

Amphibian Alloherpesviruses

RaHV-1 causes adenocarcinomas in leopard frogs (Lucké's adenocarcinoma). The tumor can grow extensively and metastasize, involving and invading other organs. Papillary projections are often observed in the neoplastic mass. Differently, the only reported

A – Fish alloherpesviruses

B – Amphibian alloherpesviruses

lesion associated with RaHV-2 is the occurrence of severe edema in frogs infected at larval stages. RaHV-3-associated disease is characterized by multifocal to coalescent gray skin patches scattered throughout the integument of affected frogs, which correspond to areas of prominent epidermal hyperplasia during microscopic examination (Fig. 3(B)). Large numbers of intranuclear eosinophilic inclusions are seen in the thickened epidermis. Toads infected with BfHV-1 show similar but distinct skin lesions. Relatively flat to slightly elevated, dark brown, cauliflower-like skin proliferations are observed grossly. Histologically, the lesions correspond to areas of epidermal hyperplasia, frequently associated with hyperkeratosis. Intranuclear inclusions are seen in infected toads, but less numerous and prominent than in frogs infected with RaHV-3. Interestingly, minimal to no associated inflammation is observed in both infections.

Diagnosis

Diagnosis of alloherpesvirus infection can rely on various methods. First, diagnosis can be oriented by analysis of the clinical signs, anatomopathological and histopathological lesions. However, the latter are only indicative of the alloherpesvirus infection due to the absence of known pathognomonic signs and the high frequency of multipathogen co-infection. Still, hyperplastic epidermal lesions are typical and very indicative of some alloherpesvirus infections (SalHV-4, CyHV-1, RaHV-3, BfHV-1).

Specific diagnosis involves the use of viral isolation using specific cell lines, viral detection using molecular methods or serological methods. Viral isolation of most alloherpesviruses has been achieved using cell lines. Nevertheless, viral isolation is still restricted by the absence of permissive cell lines: for example, among batrachoviruses, only RaHV-2 has been successfully isolated in cell culture. Specific molecular methods are now available for detection of most alloherpesviruses (PCR, qPCR, monoclonal and polyclonal antibodies). These methods can be tentatively used to diagnose productive, but also potentially latent infection (PCR, qPCR). Regarding the latter, the specific sites of alloherpesvirus latency are frequently unknown. Viral DNA can be detected in the brain and B lymphocytes of fish previously exposed to CyHV-3. Note that the sensitivity of the molecular tools developed could be decreased by the limited knowledge about genetic coalescence within each alloherpesvirus species. Detection of the antibody response against alloherpesviruses (ELISA, seroneutralization) can help to diagnose a previous (latent) infection (e.g., screening of broodstocks). Nevertheless, interpretation should be cautious, as specific antibody half-life is rather short in fish. Specific antibodies against CyHV-3 can barely be detected from sera of fish 280 days post infection. Finally, on-site diagnostic methods including lateral flow devices and loop-mediated isothermal amplification have been developed for some alloherpesviruses.

Management and Treatment

Alloherpesviruses are not equally threatening the aquaculture sector. Some alloherpesvirus infections, like those induced by SalHV-1, were found to have limited impact on aquaculture. Other alloherpesviruses (e.g., IchV-1), can be controlled by management procedures (screening of broodstocks, disinfection of facility and incoming water, microbiological independence of produced fish batches), improving rearing conditions (fish density, water quality, stress reduction) or by regulating the water temperature.

As explained above, alloherpesvirus replication and disease expression correlates strongly with environmental temperature. This peculiarity has been exploited for the treatment of alloherpesvirus infection by changing environmental temperature to levels suboptimal or non-permissive for viral replication. For example, fish infected by CyHV-3 can be transferred to non-permissive

Fig. 3 Illustration of typical clinical features observed during some alloherpesvirus infection. Panel A. Illustration of clinical features induced by fish alloherpesviruses. (a) channel catfish (*Ictalurus punctatus*) infected by IchV-1, typical exophthalmia and distended abdomen caused by ascite. (b) Multiple plaques of epidermal proliferation (arrows) in a fingerling of Siberian sturgeon (*Acipenser baeri*) infected AciHV-2. (c) Severe papillomas caused by SalHV-4 in wild young Atlantic salmon (*Salmo salar*) captured at 10°C. (d) Proliferative cutaneous lesions in adult koi carp (*Cyprinus carpio*) infected by CyHV-1, multifocal to coalescing, slightly raised to nodular, white cutaneous proliferations along the dorsum, mouth, and pectoral fins. (e) Koi carp (*Cyprinus carpio*) infected by CyHV-3, extensive circular necrosis of the skin covering the body (black arrows), fin erosion (white arrowheads), and hemorrhages on the skin and fins (black arrowheads). (f) Diseased cultured European eel (*Anguilla anguilla*) with AngHV-1 infection. The eel shows a patchy pattern of hemorrhages in the skin, and severe hemorrhagic fins. Panel B. Illustration of clinical features induced by amphibian alloherpesviruses. (g) Multifocal to coalescent light tan to gray patches of skin are present, more frequently on the dorsum and along the flanks of a common frog (*Rana temporaria*) (black arrows). (h) Bufonid herpesvirus 1 infected common toad (*Bufo bufo*) associated gross skin lesions. Multifocal raised, dark brown, patchy areas of skin are scattered over the dorsum of the toad (black arrows). (i) Skin, Common frog (*Rana temporaria*) naturally infected with Ranid herpesvirus 3. The epidermis is focally, severely elevated (hyperplastic), forming a papillary projection (arrowhead) characterized by several clear spaces (epidermal vacuoles) partially filled with degenerating and necrotic keratinocytes. The underlying dermis shows loosely arranged collagen fibers (edema-two asterisks) and variably ectatic mucous glands (three asterisks). (j) Skin, Common toad (*Bufo bufo*) naturally infected with Bufonid herpesvirus 1. The epidermis is diffusely thickened (hyperplasia) up to 5 times as normal. Among the several nuclei are a number of intranuclear eosinophilic inclusions (inset, asterisks). The underlying dermis is characterized by loose collagen fibers (edema). (a) Courtesy of J. A. Plumb. Table 3 Clinical features caused by some alloherpesviruses

<i>Viral name</i>	<i>Susceptible host</i>	<i>Clinical signs (non-exhaustive)</i>	<i>Mortality</i>
Batrachovirus			
Ranid herpesvirus 1	Northern leopard frog (<i>Lithobates pipiens</i>)	Renal adenocarcinoma	Unknown
Ranid herpesvirus 2	Northern leopard frog (<i>Lithobates pipiens</i>)	Unclear, severe edema when infected at larval stage	Unknown
Ranid herpesvirus 3	Common frog (<i>Rana temporaria</i>)	Proliferative dermatitis	Unknown
Cyprinivirus			
Cyprinid herpesvirus 1	Common carp (<i>Cyprinus carpio</i>)	Systemic disease in fry, hyperplastic cutaneous proliferation (papillomas, pox-like lesions) in surviving/older fish	Up to 87.5% (fry)
Cyprinid herpesvirus 2	Goldfish (<i>Carassius auratus</i>), gibel carp (<i>Carassius gibelio</i>)	Lethargy, anorexia, pale patches and hypersecretion of mucus in the gills, hemorrhages on the body and gills	Up to 100% (all ages)
Cyprinid herpesvirus 3	Common carp (<i>Cyprinus carpio</i>)	Lethargy, anorexia, hypersecretion of mucus on the skin, hyperemia of the fins, skin fin & gill necrosis, fin erosion, hemorrhages on the skin, neurological symptoms	Up to 100% (all ages)
Anguillid herpesvirus 1	Japanese and European eel (<i>Anguilla japonica</i> and <i>A. anguilla</i>)	Decreased growth rates, hemorrhages and ulcerative lesions on the skin (head, beak and caudal abdominal surface) fin and gills	Up to 10%
Ictalurivirus			
Ictalurid herpesvirus 1	Channel catfish (<i>Ictalurus punctatus</i>), striped catfish (<i>Pangasius hypophthalmus</i>)	Reduced growth rates, erratic swimming, distended abdomen, hemorrhages, exophthalmia	>90% (fry and fingerling channel catfish), 30%–40% (striped catfish)
Ictalurid herpesvirus 2	Black bullhead catfish (<i>Ameiurus melas</i>)	Erratic swimming, hemorrhages	High mortality (fry and juveniles)
Acipenserid herpesvirus 2	Sturgeon species (<i>Acipenser</i> spp.)	Erratic swimming, lethargy, hyperplastic skin lesions, hyperemia of the ventral scutes, mouth and anus	Up to 80% (juvenile white sturgeon), up to 100% (juvenile Siberian sturgeon)
Salmonivirus			
Salmonid herpesvirus 1	Rainbow trout (<i>Oncorhynchus mykiss</i>)	Darkened pigmentation, exophthalmia, abdominal distention, haemorrhages in the fins, pale gills	Low
Salmonid herpesvirus 2	Salmon and trout (<i>Oncorhynchus</i> spp.)	Lethargy, anorexia, darkened appearance, skin ulcers, focal epithelial proliferation on the mouth and body, exophthalmia Epithelial tumors (papilloma), preferably on the mouth, in surviving fish	Up to 100%. High losses in juveniles
Salmonid herpesvirus 3	Lake trout (<i>Salvelinus namaycush</i>)	Lethargy, swim near the surface, behavioral modification, mucoid patches on the skin, hemorrhages on eyes and jaw	Up to 100%. High losses in juveniles
Unclassified			
Acipenserid herpesvirus 1	White sturgeon (<i>Acipenser transmontanus</i>)	Few external clinical signs associated with a diffuse hyperplastic dermatitis	Up to 35% (juvenile white sturgeons)
Bufoid herpesvirus 1	Common toad (<i>Bufo bufo</i>)	Proliferative dermatitis	Unknown
Esocid herpesvirus 1	Northern pike (<i>Esox lucius</i>)	Whitish circular plaques on the fins and dorsal parts	NA
Salmonid herpesvirus 4	Atlantic salmon (<i>Salmo salar</i>)	White plaques of epithelial tumors (papilloma) on skin, or caudal peduncle	>50% when secondary infections involved
Salmonid herpesvirus 5	Lake trout (<i>Salvelinus namaycush</i>)	Abnormal swimming, discolored musculature	

water temperatures (>30°C), allowing fish to clear viral infection and develop an adaptive immune response. This method was also used as a natural immunization method following iatrogenic CyHV-3 contamination. Unfortunately, fish infected with these methods may become latently infected by CyHV-3. Interestingly, fish infected by CyHV-3 have been shown to naturally seek for warmer environments (behavioral fever), thereby surviving viral infection; this feature could be exploited in aquaculture. The specific temperature range allowing alloherpesvirus replication and disease is variable among viral species. For instance, eel farms experiencing AngHV-1 infection usually decrease environmental temperature to decrease clinical signs and mortality.

Antiviral treatments were tested against alloherpesviruses, but to the best of our knowledge, no commercial treatment is currently available. Extracts of the *Clinacanthus nutans* (Burm. f.) Lindau medicinal plant used as a prophylactic or therapeutic treatment against CyHV-3 infection showed positive effects on common carp survival. Nucleoside analogues such as acyclovir are able to limit IchV-1, CyHV-3 or SalHV-2 replication in cell culture, and to be effective against SalHV-2 *in vivo*.

Prevention

Facing the lack of efficient therapeutic methods, safe and efficacious vaccines represent the most promising control approach against alloherpesviruses. Vaccination of fish should involve delivery methods adapted to mass vaccination of the target species, minimizing the cost for vaccination and maximizing the duration of immunity with an early in life and limited number of vaccine administrations.

Multiple vaccine candidates against alloherpesviruses have been studied but very few are commercially available nowadays. Inactivated vaccines consist of the entire killed viral particle, thus containing all structural viral antigens. Inactivated vaccine candidates have been described for SalHV-2, CyHV-2 and CyHV-3. Injection of inactivated CyHV-2 vaccines to gibel carp induced partial protection. A formalin-inactivated CyHV-3 vaccine, trapped within a liposomal compartment and used for oral administration, induced partial protection. The high amount of viral antigen required, the vaccine delivery method, and a generally low efficacy are the main concerns and restrictions for inactivated vaccine development.

DNA vaccines consist of genetically engineered DNA plasmids encoding specific antigens from pathogens. DNA vaccines were tested against ICHV-1 and CyHV-3. Injectable DNA vaccines consisting of plasmids encoding CyHV-3 ORF25 envelope glycoprotein were shown to be partially efficacious against immersion challenge, but not against a cohabitation challenge. Attempts to deliver the DNA plasmids encoding ORF25 orally failed to induce an efficient protection. DNA vaccines against ICHV-1 showed equivocal results, even when cocktails of plasmid DNA encoding multiple ORFs were used. Studies on DNA vaccines against alloherpesviruses highlighted two main challenges for future research, namely selecting the best antigens for immunization and improving vaccine delivery methods.

Attenuated vaccines consist of live viral strains with a virulence that has been reduced or suppressed by serial passages in cell culture (conventional attenuated vaccine) or by targeted viral genome editing (recombinant attenuated vaccine). Attenuated vaccines have the advantages of being compatible with mass vaccination and simulating a natural viral infection of the host. However, they raise safety concerns including residual virulence, reversion to virulence, and spread from vaccinated to naïve subjects. Conventional and recombinant attenuated vaccines were developed against ICHV-1 and CyHV-3. A conventional anti-CyHV-3 attenuated vaccine has been developed by serial passages in cell culture and UV irradiation. This vaccine is commercialized in Israel for the vaccination of koi and common carp. The determinism of the attenuation is unknown, and consequently, reversions to a pathogenic phenotype cannot be ruled out. The attenuated strain has residual virulence for fish weighing less than 50 g.

Due to scientific advances in molecular biology and molecular virology, the development of attenuated vaccines is evolving from empirical to rational design. A viral genome can be edited to delete genes encoding virulence factors in such a way that reversion to virulence cannot occur. This approach has been tested for CyHV-3 by targeting different genes such as the thymidine kinase (TK) and deoxyuridine triphosphatase. The previous cloning of ICHV-1 and CyHV-3 as infectious bacterial artificial chromosomes (BAC) allows viral mutagenesis. Recently, a vaccine candidate based on the double deletion of ORF56 and ORF57 was produced using BAC mutagenesis. This strain is safe for vaccinated fish, is limitedly transmitted to naïve fish and induces full protection against a lethal cohabitation challenge. ORF57 was found to be the crucial virulence factor and is conserved in the genus *Cyprinivirus*. A recombinant attenuated vaccine candidate was also developed for ICHV-1 by deletion of the TK gene and was shown to be effective. Attenuated recombinant vaccines, associated with the tools provided by BAC mutagenesis, allow efficient development of vector vaccine strategies. Fish immunized with an ICHV-1 TK deleted recombinant attenuated strain expressing a reporter gene developed an antibody response against the transgene product.

Glossary

Cytopathic effect Morphologic changes in cells resulting from virus replication.

Dysplasia An abnormality in the appearance of cells and indicative of a preneoplastic change.

Hyperplasia An increase in the number of cells of an organ or tissue.

Leiomyosarcoma Neoplasia of smooth muscle cells.

Malpighian cells Cells of the deepest layer of the epidermis.

Neoplasia An abnormal growth of cells.

Oncogene Cellular or viral gene whose products are capable of inducing a neoplastic phenotype.

Proto-oncogene A normal cellular gene which when inappropriately expressed or mutated becomes an oncogene.

Introduction

Retroviruses have been documented in a wide range of vertebrate species including lower vertebrates such as frogs, snakes, sharks, fish, birds, and turtles. To date, however, the majority of these reported sequences represent only partial fragments of the retrovirus. In recent years, the complete genomic sequence of exogenous fish retroviruses from Atlantic salmon (*Salmo salar*), walleye (*Sander vitreus*), and snakehead (*Ophicephalus striatus*), and an endogenous retrovirus of zebrafish (*Danio rerio*) have been determined. Analysis of these viral genomes indicates a high degree of diversity among the fish retroviruses as well as several unique features compared to mammalian and avian retroviruses.

The etiological relationship between retroviruses and cancer is well established in mammalian and avian systems. Simple retroviruses can promote cell proliferation by inducing the ectopic expression of captured cellular oncogenes (viral transduction for acutely transforming viruses) in which an oncogene recombines into the viral genome, or by integration near or within the coding sequence of cellular proto-oncogenes (nonacute transforming viruses). Transcription factors encoded by some complex retroviruses, like human T-cell leukemia virus-1 (HTLV-1), also have nonacute oncogenic potential by deregulating cellular pathways controlling cell proliferation.

Like their mammalian and avian counterparts, many fish neoplastic/proliferative diseases are suspected of having a retroviral etiology. Retroviruses are reported to be associated with 13 spontaneous proliferative diseases of fish based on the observation of retrovirus-like particles and, in some cases, reverse transcriptase activity in neoplastic lesions. Seven of these diseases with putative viral etiologies display a seasonal cycle, that is, they develop and regress annually. Retrovirus-associated tumors of the skin have received the most attention, since they are most visible and easily sampled. Skin tumors with suspected viral etiologies have been found in white sucker (*Castostomus commersoni*), walleye, yellow perch (*Perca flavescens*), and European smelt (*Osmerus eperlanus*). Retroviruses have also been linked to lymphoma in northern pike (*Esox lucius*), leukemia in chinook salmon (*Oncorhynchus tshawytscha*), and leiomyosarcoma of the swimbladder in Atlantic salmon. One noteworthy piscine retrovirus, the snakehead fish retrovirus (SnRV), has not been associated with tumor induction. In most of these systems, the etiologic relationship of retroviral infections and neoplasms rests on circumstantial evidence such as observations of viral particles by electron microscopy and the presence of reverse transcriptase activity. However, sequencing of fish retroviruses has facilitated use of molecular-based diagnostic reagents and, in some cases, shed light on potential modes of pathogenesis. In particular, the walleye retroviruses, walleye dermal sarcoma virus (WDSV) and walleye epidermal hyperplasia virus type 1 (WEHV-1) and type 2 (WEHV-2), express a subset of accessory genes exclusively during oncogenesis, specifically implicating the encoded proteins in the process of tumorigenesis.

Retroviruses and their Life Cycle

Retrovirus particles are composed of viral structural and enzymatic proteins and two copies of the positive-sense single-stranded RNA genome. The proteins are surrounded by a lipid bilayer, acquired from the host cell, in which viral envelope glycoproteins are embedded. Retroviral infection is initiated when the surface glycoprotein binds to its cognate receptor on the surface of a susceptible cell. Upon fusion of the viral and cellular membranes, the viral core enters the cytoplasm where the virally encoded enzyme, reverse transcriptase, copies the RNA genome into DNA. The viral integrase protein binds reverse transcribed DNA and mediates its integration into the genomic DNA of the host. In rare cases, retroviral infection of host germ-line cells and subsequent integration into the chromosomes can establish retroviral sequences as heritable genetic elements, known as endogenous retroviruses.

Fig. 1 (a) Gross and histological images of walleye dermal sarcoma and (b) walleye epidermal hyperplasia.

Based on the complexity of the viral genome, retroviruses can be divided into two broad categories: simple and complex. Simple retroviruses, including members of the *Gammaretroviruses* and *Alpharetroviruses*, contain three genes: *gag*, *pol*, and *env*. Expression of a full-length unspliced messenger RNA (mRNA) and a spliced mRNA serve as the templates for translation of the retroviral structural and enzymatic proteins. These proteins are first translated as polyproteins from *gag* and *pol*, respectively, and are processed by a virally encoded protease. The viral envelope glycoprotein is encoded from a singly spliced viral transcript containing the *env* gene.

Complex retroviruses are distinguished from simple retroviruses on the basis of their additional coding capacity and pattern of viral gene expression. This category of retroviruses includes *Lentiviruses* such as human immunodeficiency virus type 1 (HIV-1), *Spumaviruses*, and the *Deltaretroviruses*, human T-cell leukemia virus (HTLV-1), and bovine leukemia virus (BLV). Complex retroviruses produce multiply spliced transcripts that encode two classes of accessory/regulatory proteins. One class includes transcriptional regulatory proteins such as HTLV-1 Tax and HIV-1 Tat, which act *in trans* to directly regulate the activity of the viral promoter. A second class, including HTLV-1 Rex and HIV-1 Rev, act post transcriptionally, to facilitate transport of unspliced and singly spliced viral transcripts to the cytoplasm. The combined action of these proteins divides the replication cycle into two temporal phases: an early, regulatory phase, and a later, structural phase. During the regulatory phase, low levels of fully spliced transcripts encoding *trans*-activators increase levels of transcription leading to the accumulation of post-transcriptional regulatory proteins. These proteins allow production of unspliced and singly spliced mRNAs that encode the viral structural proteins.

Both simple and complex retroviruses have been identified in fish species. Retroviruses isolated from walleye and snakehead fish resemble complex retroviruses based upon their genome structure and transcriptional profile, while simple retroviruses have been identified in Atlantic salmon and zebrafish.

Skin Tumors in Walleye and Their Associated Retroviruses

Walleye dermal sarcoma (WDS) and walleye discrete epidermal hyperplasia (WEH) are neoplastic and hyperplastic skin lesions in walleye that have been etiologically associated with infection by three distinct retroviruses (Fig. 1). WDS and WEH were first reported in 1969 on fish from Oneida Lake in New York. Since then, WDS and WEH have been reported on walleyes throughout North America. These diseases have a seasonal cycle; tumor incidence is highest in the late fall and early spring months at frequencies of 27% and 5% for WDS and WEH, respectively. Lower tumor prevalence in summer months is associated with regression on individual adult fish.

WDS appears as a cutaneous mesenchymal neoplasm arising multicentrically within the superficial dermis and overlaid with epidermis. Fall tumors appear highly vascularized due to a network of capillaries, while spring tumors are frequently white with ulcerated surfaces. Invasive tumors are rarely observed in feral fish. WEH lesions are benign mucoid-like plaques with distinct boundaries. They can range from 2 to 3 mm in diameter to large lesions with irregular borders that may be as large as 50 mm across. Histologically, this disease appears as an epidermal proliferation consisting primarily of Malpighian cells.

Experimental transmission of WDS and WEH has been achieved with cell-free filtrates. Interestingly, only cell-free filtrates prepared from the spring, regressing WDS, not fall, developing WDS, are able to transmit disease. Infection of walleye fingerlings less than 9 weeks of age results in the frequent development of invasive tumors.

Electron microscopic observation of retrovirus particles and cell-free transmission of both diseases suggest a retroviral etiology for WDS and WEH. WDSV was isolated from WDS tissue, and two independent retroviruses, WEHV1, WEHV2, were isolated from

Fig. 2 Genomic and transcriptional maps of WDSV, WEHV1, and WEHV2. Genomic organization of viral DNA with retroviral genes and accessory genes *orfa*, *orfb*, and *orfc* is depicted under each virus heading. The envelope-spliced transcript (*env*) and additional spliced transcripts (*A* and *B*), which are capable of expressing accessory genes, are illustrated. The vertical dashed lines indicate the boundaries of the exons, introns, and open reading frames.

WEH lesions. Similar hyperplastic lesions on yellow perch in Oneida Lake are associated with two new retroviruses, perch epidermal hyperplasia virus types 1 and 2 (PEHV1, PEHV2).

Isolation and Sequencing of Retroviruses from WDS and WEH Lesions

WDSV, WEHV1, and WEHV2 have been molecularly cloned and sequenced (Fig. 2). The genome structures of WDSV, WEHV1, and WEHV2 indicate large and complex viral genomes (12.7, 12.9, and 13.1 kbp, respectively). All three viruses have intact open reading frames (ORFs) capable of encoding the structural and enzymatic genes *gag*, *pol*, and *env*. *gag* (viral capsid) and *pol* (reverse transcriptase) are in the same reading frame and synthesized as a polyprotein through a termination suppression mechanism. *pro* (viral protease), responsible for cleaving the polyprotein, is located in the same reading frame as *pol*. A unique feature of all three viruses is the presence of additional orfs that have tentatively been called *orfa*, *orfb*, and *orfc*. The *orfa* and *orfb* genes are located between *env* and the 3' long terminal repeat (LTR), while *orfc* is located between the 5' LTR and the start of *gag*. Database searches with OrfA protein amino acid sequences suggest limited homology with D-type cellular cyclins within the cyclin-box motif, and are referred to as rv-cyclins. WEHV1 rv-cyclin has a 20% amino acid identity and 35% similarity with human cyclin D-3, whereas WEHV2 and WDSV rv-cyclin are most similar to human cyclin D-1 (22%/35% and 19%/29% amino acid identity/similarity). Similarities with known walleye and other piscine cyclins are not significantly greater. The WEHV cyclin homologs are 37% identical within the cyclin box motif and 21–28% identical with the WDSV cyclin. Sequence homologies between rv-cyclin and OrfB in the walleye retroviruses suggest they arose by a gene duplication event.

Roles of the WDSV Accessory Proteins in Pathogenesis

Transcriptional mapping by RT-PCR and Northern blot analyses of developing and regressing WDS and WEH have demonstrated temporal gene expression profiles and complex splicing patterns analogous to those seen in the complex retroviruses of mammals. In developing WDS tumors, only low levels of multiply spliced subgenomic transcripts are detected. These transcripts predominantly contain the coding sequences for rv-cyclin and OrfB. Regressing spring tumors contain high levels of full-length and subgenomic transcripts as well as unintegrated viral DNA and transmissible virus. OrfC is likely encoded by the full-length transcript coincident with tumor regression.

A detailed transcriptional analysis of WDSV showed an alternative splicing pattern of the *orfa* transcript (Fig. 2). In developing tumors, the *orfa* transcript contains the coding sequence for a full-length rv-cyclin protein that localizes to the nucleus of mammalian and walleye cells. Alternatively spliced forms of this transcript encode amino-terminal truncated forms of the rv-cyclin protein, which localize in the cytoplasm of cells. The different forms of rv-cyclin may play functionally different roles in developing and regressing tumors. A single, spliced transcript encodes the OrfB protein, which is predominantly localized in the cytoplasm in tumor explant cells, but is capable of shuttling into and out of the nucleus when expressed in piscine and mammalian cells.

The OrfC protein from WDSV has been shown to localize to mitochondria and to disrupt mitochondrial function, which results in apoptosis. Only the full-length viral transcript found in regressing tumors is capable of encoding OrfC. Apoptotic cells are present in regressing, but not developing, WDS tumor sections. Therefore, the OrfC protein may be responsible for a direct viral mechanism of tumor regression.

WDSV *orfa* and *orfb* are the only virus transcripts found in developing tumors, suggesting direct roles for rv-cyclin and OrfB in the process of tumorigenesis, and their oncogenic potential has been demonstrated by several experimental approaches. WDSV *orfa* supported growth of a yeast (*Saccharomyces cerevisiae*) strain conditionally deficient for the synthesis of the G1 to S cyclins that are necessary for cell cycle progression. WEHV *orfa* did not support yeast growth in this model. Transgenic expression of WDSV *orfa* in mice from a skin-specific promoter caused a moderate to severe squamous epithelial hyperplasia and dysplasia dependant on skin injury. This suggests that rv-cyclin is not oncogenic as a result of a 'single-hit' mechanism, but rather, that secondary genetic or epigenetic events (possibly wound repair) are necessary for tumor development and progression. A similar phenotype has been described in transgenic mice expressing *v-jun* oncogene from the H-2K^k major histocompatibility complex (MHC) class I antigen gene promoter. When expressed in mammalian or piscine cell culture, WDSV rv-cyclin localized in the nucleus and was found by co-immunoprecipitation to be associated with cyclin dependent kinase 8 and cyclin C, general transcription initiation factors, and RNA polymerase II transcription complexes. In piscine cells, rv-cyclin inhibited transcription from the WDSV promoter independent of *cis*-acting DNA sequences. However, rv-cyclin can activate other viral promoters in fish cells, and can activate the WDSV promoter in select mammalian cells; thus rv-cyclin activation and inhibition of transcription are dependent on both the promoter and the cell type. WDSV rv-cyclin contains a defined transcription activation domain in the carboxy end of the protein, and the isolated activation domain is capable of interacting with co-activators of transcription. WEHV rv-cyclins do not have a corresponding carboxy-region activation domain. WDSV rv-cyclin may exhibit oncogenic potential by differential regulation of host gene expression such as proto-oncogenes or tumor suppressors.

Less is known about the capabilities of the OrfB protein, but initial studies indicate its direct association with the regulation of signal transduction pathways. It is concentrated, in tumor explant cells, at focal adhesions, and along actin stress fibers. Established OrfB-expressing lines are resistant to the chemical induction of apoptosis, suggesting a role in oncogenesis.

The origins of the accessory genes of complex retroviruses are unclear. This includes the origins of the WDSV accessory genes encoding rv-cyclin, OrfB, and OrfC. In the case of rv-cyclin and OrfB, their extreme divergence from host cyclin sequences indicates that any transduction event was ancient and led, ultimately, to an exclusive, complex viral species. The OrfC protein, like the accessory proteins of other complex retroviruses, has no clear homology to host proteins.

Control of the Seasonal Cycle of Disease

An interesting aspect of WDS is the control of the seasonal switch in viral gene expression and associated tumor regression. Potential modulators of viral gene expression include host immunity and endocrine activity (accompanying spawning) and environmental factors such as water temperature, physical trauma, and sunlight. A number of *cis*-acting elements important for transcription activation have been identified in the WDSV promoter. There is differential binding of proteins from developing and regressing tumor nuclear extracts to a 15 bp repeat region in the WDSV promoter. This element may be critical to the induction of high levels of virus expression. The WDSV rv-cyclin protein negatively regulates the WDSV promoter in tissue culture cells. Presumably, it is advantageous for the virus to have lower levels of gene expression during tumor development to avoid immune surveillance as well as the cytopathic effects associated with virus production. While rv-cyclin may function in the repression of virus expression during tumor growth, the host, environmental, or viral signals that switch on full virus expression are yet to be determined.

Fig. 3 Genomic and transcriptional map of SnRV. Predicted coding regions are shown as open or shaded boxes. The envelope-spliced transcript (*env*) and additional spliced transcripts (*a*, *b*, *c*), which are capable of expressing accessory genes, are illustrated. LP indicates the location of a predicted leader peptide. The vertical dashed lines indicate the boundaries of the exons, introns, and open reading frames.

Snakehead Retrovirus

The SnRV was isolated from a productively infected cell line derived from a Southeast Asian striped snakehead fish. Cell culture supernatant from these infected cells demonstrated high levels of RT activity and the presence of type C-like retrovirus particles. Additionally, supernatant from the infected cell line induced cytopathic effects in cultures of a bluegill cell line (BF-2).

Molecular approaches were utilized to identify and sequence the SnRV from infected cells. The large 11.2 kbp genome of SnRV contains intact coding regions for *gag*, *pol*, and *env* (Fig. 3). An arginine tRNA primer binding site used for reverse transcription initiation distinguishes SnRV from other retroviruses. The structure and transcriptional profile of SnRV suggests a complex expression pattern capable of encoding an ORF located between *env* and the 3' LTR and two very small ORFs termed ORF1 and ORF2. Within the leader sequence of SnRV resides a start codon located just upstream of the major splice donor site that could potentially encode a 14 amino acid peptide (LP). Expression of Env from a singly spliced transcript is predicted to utilize the LP initiation codon and fuses this 14 amino acid peptide in frame to downstream *env* sequences. A transcript with four exons and two initiator codons would encode ORF1 and ORF2 proteins. The 3' ORF would be expressed from a transcript containing three exons and would encode a protein of 24 kDa. Finally, the fourth spliced transcript may encode 3' ORF or possibly a LP-Env cytoplasmic domain (CD) fusion protein. The 3' ORF contains an N terminal acidic domain, cysteine residues, and a basic region, motifs commonly found in transcriptional activators. These small ORFs have no significant homology to any known proteins in the databases, and their role in the viral life cycle is unknown. No endogenous copies of SnRV have been identified in the snakehead genome and an uninfected cell line has been established.

Although the presence of SnRV in wild populations has not been thoroughly examined, the virus has been independently isolated from two separate snakehead cell lines derived from whole fry tissue and from caudal peduncle tissue from juvenile fish. In all cases, fish from which these cell lines were derived appeared healthy.

Salmon Swimbladder Sarcoma-Associated Retrovirus

An outbreak of neoplastic disease of the swimbladder of Atlantic salmon was first reported at a Scottish commercial marine fish farm in 1975. Affected salmon were sluggish and in poor condition. A viral etiology was suspected, and electron microscopic evaluation of tumors revealed the presence of budding viral particles with retroviral morphology. A second outbreak occurred between 1995 and 1997 in brood stock salmon held at the North Attleboro National Fish Hatchery in Massachusetts. The fish exhibited skin discoloration and hemorrhages on the fins and body and showed a general debilitation and lack of vigor. In May of 1997, significant mortality was noted at the facility such that 35% of the population was affected by late spring of 1998. All of the affected fish displayed swollen abdomens due to multinodular masses on internal and external surfaces of the swimbladder. In several cases, these multinodular masses occupied the entire swimbladder (Fig. 4). Histologic examination revealed that the tumors were composed of well-differentiated fibroblastic cells that were arranged in interlacing bundles, which were classified as leiomyosarcomas.

Isolation of a Retrovirus from Salmon Swimbladder Sarcoma

An exogenous retrovirus, termed Atlantic salmon swimbladder sarcoma virus (SSSV), was initially identified in tumors by degenerate RT-PCR of tumor RNA, and the entire viral sequence completed by DNA sequencing of proviral DNA. In contrast to the complex walleye retroviruses, SSSV is a simple retrovirus. The viral genome contains ORFs capable of expressing *gag*, *pol*, and *env* (Fig. 5). Additionally, a short 25 amino acid leader peptide of unknown function is located upstream of the Gag-Pol polyprotein

Fig. 4 (a) Gross and (b) histological images of Atlantic salmon swimbladder sarcoma.

Fig. 5 Genomic and transcriptional map of SSSV. Predicted coding regions are shown as open boxes. The envelope-spliced transcript (*env*) is illustrated. LP indicates the location of a predicted leader peptide. The vertical dashed lines indicate the boundaries of the exons, introns, and open reading frame.

ORF. SSSV differs from other simple retroviruses by not having related endogenous sequences in the host genome, and SSSV is the only retrovirus to use a methionine-tRNA as a plus-strand primer. Additionally, sequences in *pol* display homology to central polypurine tract regions identified in complex retroviruses. Central polypurine tracts facilitate the formation of a single-stranded DNA region called a central DNA flap as a result of reverse transcription priming from this internal site. In HIV-1, this feature plays a major role in complex retroviral replication and allows efficient infection of nondividing cells. It is intriguing that SSSV displays a high proviral copy number (greater than 30 copies per cell) with a polyclonal integration pattern in swimbladder tumors. SSSV must be capable of initiating multiple rounds of infection within the same cell. The specific mechanisms leading to the high copy number and its implications in the pathogenesis of disease are of significant interest for future research.

Sequence Comparisons of SSSV with Other Retroviruses

A comparison of the sequence of SSSV viral proteins with other retroviruses indicates large regions of homology with mammalian type C and type D viruses in *Pol* and *Env*. Additionally, a 179 amino acid region in the C terminus of *Gag* and a 1064 amino acid region of *Pro-Pol* displays 23% and 33% identity to the related WDSV proteins, respectively. SSSV has striking homology to the sequence of the zebrafish endogenous retrovirus (ZFERV). BLAST analysis of the *Gag*, *Pol*, and *Env* ORFs of SSSV reveals a 25% identity with ZFERV over 533 amino acids within *Gag*, a 40% identity over 533 amino acids of *Pol*, and a 39% identity over 429 amino acids of *Env*.

Prevalence, Seasonality, and Transmission of SSSV

A PCR diagnostic assay was developed using sequences within the *pol* gene of SSSV. Prevalence at the North Attleboro fish facility has been found to be 52% and 5% of a natural stock of Pleasant River salmon were found to harbor SSSV.

Like other retroviral diseases of fish, observations suggest that salmon swimbladder sarcoma is seasonal. First, of the 34% fish mortality at the North Attleboro facility between 1997 and 1998, 57% occurred in June. Second, in the following year, the surviving salmon had an SSSV incidence (measured by PCR) that cycled with a peak in late summer to early winter and then diminished in late winter to early spring. The period of highest SSSV incidence correlated with salmon spawning runs in late fall.

Fig. 6 Unrooted phylogenetic tree of representative retroviruses based on an amino acid alignment of seven conserved domains in reverse transcriptase. Retroviruses are designated as follows: MPMV (Mason–Pfizer monkey virus), JSRV (Jaagsiekte sheep retrovirus), MMTV (mouse mammary tumor virus), RSV (Rous sarcoma virus), EIAV (equine infectious anemia virus), FIV (feline immunodeficiency virus), Visna (visna virus), HIV-2 (human immunodeficiency virus-2), HIV-1 (human immunodeficiency virus-1), SIV-agm (simian immunodeficiency virus-agm), HTLV-1 (human T-cell leukemia virus type 1), HTLV-2 (human T-cell leukemia virus 2), BLV (bovine leukemia virus), SSSV (salmon swimbladder sarcoma virus), SnRV (snakehead retrovirus), BFV (bovine foamy virus), HFV (human foamy virus), FeLV (feline leukemia virus), MLV (murine leukemia virus), GALV (gibbon ape leukemia virus), WDSV (walleye dermal sarcoma virus), WEHV-1 (walleye epidermal hyperplasia virus type 1), WEHV-2 (walleye epidermal hyperplasia virus type 2), ZFERV (zebrafish endogenous retrovirus), Xen-1 (Xenopus endogenous retrovirus-1).

Interestingly, WDSV prevalence, which peaks during late spring, also correlates with the time of spawning. This suggests that endocrine changes during spawning runs may be a critical factor in the observed seasonal variation in disease incidence.

Pathogenesis of SSSV

The existence of SSSV sequences in association with an outbreak of the swimbladder sarcoma suggests a role for the retrovirus in pathogenesis of the disease. As a simple retrovirus with no transduced cellular oncogenes, one possible mechanism of tumorigenesis is the insertional activation of a cellular proto-oncogene. The high copy number of proviruses in tumors has made the analysis of insertional activation events difficult, but multiple insertions increase the likelihood of such a mechanism. It is also feasible that SSSV may express an oncogenic viral gene product. This mechanism of oncogenesis has been proposed for the Jaagsiekte sheep retrovirus (JSRV) in the induction of ovine pulmonary adenocarcinoma and in Friend spleen focus-forming virus (SFFV)-associated erythroid hyperplasia in mice. Additionally, the presence of common integration sites within JSRV-associated tumors suggests that insertional mutagenesis may act in concert with the envelope in tumor development. Thus, a multifactorial mechanism for the development of salmon swimbladder sarcoma must also be considered.

In addition to sarcoma, a number of other distinct pathologies are associated with SSSV infection. These diseases are frequently debilitating and are, therefore, of significance to the aquaculture industry. Atlantic salmon at the North Attleboro hatchery, during the SSSV outbreak, presented with multifocal hemorrhages, sloughing of the epidermis, lethargy, wasting, and failure to mature sexually in addition to swimbladder tumors.

Zebrafish Endogenous Retrovirus

Endogenous retroviruses have been identified in almost all vertebrate genomes, and most are defective due to mutations and deletions. An endogenous retrovirus, ZFERV with a genome of 11.2 kbp has been identified in the Tubingen stock of zebrafish, and contains intact coding regions for *gag*, *pol*, and *env*. The *gag* and *pol* genes are in the same reading frame. While the majority of endogenous retroviruses are transcriptionally silent because of mutation or methylation, ZFERV remains transcriptionally active. In addition to genomic transcripts that encode Gag and Pol proteins, an unusual multiply spliced *env* transcript is produced. Expression appears highest in the larval and adult zebrafish thymus, and no expression was detected in 2-day old embryos, suggesting that ZFERV expression may be tied to thymic development.

Phylogeny of Fish Retroviruses

Retroviruses have been classified into seven genera based largely on highly conserved amino acid sequences in the retroviral reverse transcriptase gene. While the majority of the viral sequences employed in this classification represent mammalian and avian retroviruses, a new genus termed *Epsilonretroviruses*, representing the fish retroviruses WDSV, WEHV-1, WEHV-2, has been added to the most recent classification. As more retroviral sequences from lower vertebrates have been identified, it has become apparent that this classification scheme may be inadequate to represent the apparent diversity.

Based on the unique characteristics of SnRV, including its genomic organization, tRNA primer, and complex transcriptional profile, the virus is yet to be definitively placed in the current classification. The large size of the genome, genetic organization, and presence of additional ORFs suggest that SnRV is closest to the spumaviruses and walleye retroviruses, but its limited sequence homology suggests SnRV is divergent from these groups.

Phylogenetic analysis indicates that, while the walleye retroviruses cluster in a group representing the *Epsilonretroviruses*, SSSV and ZFERV appear to represent a new branch of piscine retroviruses between the walleye retroviruses and the *Gammaretroviruses*, a genera that includes the murine leukemia virus (MLV)-related retroviruses (Fig. 6). The SnRV appears quite divergent from the other fish retroviruses by its placement in a distinct branch near the *Spumaviruses*. This would suggest that SnRV is quite divergent from the genus *Epsilonretrovirus* and may represent yet another group of retroviruses. Interestingly, a more encompassing phylogenetic analysis using all known retroviral sequences from lower vertebrates, including partial endogenous retroviral *pol* fragments from Stickleback (*Gasterosteus aculeatus*), brook trout (*Salvelinus fontinalis*), Brown trout (*Salmo trutta*), freshwater whiting (*Coregonus lavaretus*), and puffer fish (*Fugu rubripes*), indicates that the majority of the fish viruses, excluding SnRV, cluster together with MLV-related viruses in a group separate from most non-MLV related mammalian retroviruses. This raises the possibility that some retroviral groups maybe restricted to particular vertebrate classes. However, it is evident from the diversity among the fish retroviruses, that there is a high degree of heterogeneity within this group.

Glossary

Exophthalmia Abnormal protrusion or bulging of the eyeball

Finfish Fish with fins, as opposed to shellfish

Salmonid Fish in the family *Salmonidae*

Classification

The family *Rhabdoviridae* currently has 18 genera accepted by the International Committee for Virus Taxonomy (ICTV), and three of those genera contain fish rhabdoviruses. In the genera *Novirhabdovirus*, *Sprivirus*, and *Perhabdovirus* all viruses infect fish hosts, and there are no fish viruses in any of the other 15 rhabdovirus genera. In the overall phylogeny of the *Rhabdoviridae* the three fish virus genera are well separated from each other, and the novirhabdovirus genus occupies a position basal to all other genera (Fig. 1). The novirhabdovirus genus was established in 1998 and contains four viral species, as listed in Table 1. Two of these species contain infectious hematopoietic necrosis viruses (IHNV) and viral hemorrhagic septicemia viruses (VHSV), which are globally important fish pathogens that are well characterized in terms of molecular biology and genetic diversity, with many known genetic subgroups and strains within each species. Hiram rhabdoviruses (HIRRV) are also important pathogens but with a more restricted geographic and host range, and snakehead rhabdoviruses (SHRV) have not been extensively characterized.

The sprivirus and perhabdovirus genera were established more recently, in 2013 and 2012, respectively. There are two recognized species in the sprivirus genus (Table 1). The species *Carp sprivirus* contains a single virus, spring viraemia of carp virus (SVCV); another of the important fish pathogens that has multiple genetic subgroups distributed across the globe. The species *Pike fry sprivirus* is comprised

Fig. 1 Phylogenetic analysis of 105 animal rhabdovirus sequences illustrating relationships among 14 established genera, two proposed genera, and several unassigned viruses. Viral species in the three fish rhabdovirus genera (see Table 1) are shown as individual taxa, while taxa within other genera are collapsed into triangles to conserve space. The three fish rhabdovirus genera are shown as colored branches, and an asterisk denotes the type species in each genus. Unlabeled branches and triangles represent individual viruses and proposed genera, respectively, that have not yet been accepted by the International Committee for Virus Taxonomy. The four genera of plant rhabdoviruses are not included here. The tree results from full length polymerase (L) amino acid sequences aligned and analyzed with gaps (2246 characters) under a Bayesian implementation of the Yule speciation model, using the LG substitution model and constant population size prior. Posterior probability (pp) values above 0.7 are shown for critical nodes, and taxa within each established genus clustered with pp of 1.0. Scale bar is substitutions per site. Tree provided by Dr. Rachel Breyta, University of Washington.

Table 1 Classification of fish rhabdoviruses into 3 genera and several unassigned viruses^a

Genus	Species	Virus(es)	General host range ^b	Geography	Genome
<i>Novirhabdovirus</i>					
	<i>Salmonid novirhabdovirus</i>	Infectious hematopoietic necrosis virus (IHNV)	salmonid fish including rainbow trout	North America, Asia, Europe	GQ413939.1
	<i>Piscine novirhabdovirus</i>	Viral hemorrhagic septicemia virus (VHSV)	diverse range of marine and freshwater species, rainbow trout	Europe, Asia, North America	KC778774.1
	<i>Hirame novirhabdovirus</i>	Hirame virus (HIRRV)	olive flounder, ayu	Japan, Korea	AF104985
	<i>Snakehead novirhabdovirus</i>	Snakehead virus (SHRV)	snakehead	Southeast Asia	AF147498
<i>Sprivirus</i>					
	<i>Carp sprivirus</i>	Spring viremia of carp virus (SVCV)	wide range of cyprinid species	Europe, Asia, North America	U18101
	<i>Pike fry sprivirus</i>	Pike fry rhabdovirus (PFR) Grass carp rhabdovirus (GrcRV) Tench rhabdovirus (TenRV)	wide range of cyprinid species, pike and brown trout	Europe	JF872827 NC025376.1 KC113517.1
<i>Perhabdovirus</i>					
	<i>Perch perhabdovirus</i>	Perch rhabdovirus (PRV)	perch	Europe	JX679246
	<i>Sea trout perhabdovirus</i>	Lake trout rhabdovirus (LTRV)	brown trout varieties	Europe	AF434992
	<i>Anguillid perhabdovirus</i>	Eel virus European X (EVEX) Eel virus American (EVA)	eel	Europe, Asia	X827265
Unassigned					
		Starry flounder rhabdovirus	starry flounder	North American Pacific coast	AY450644
		<i>Siniperca chuatsi</i> rhabdovirus	mandarin fish	China	NC_008514.1
		Chinese rice-field eel rhabdovirus	Asian swamp eel	China	MH319839.1
		<i>Scophthalmus maximus</i> rhabdovirus	turbot	China	HQ003891.1

^avirus listed under the 3 genera have been established as species by the ICTV (2018 taxonomy). Viruses listed as unassigned are examples of those that have been described in the literature but are not currently recognized by the ICTV.

^bformal classification for fish hosts: salmonid, *Oncorhynchus* and *Salmo* sp.; rainbow trout, *Oncorhynchus mykiss*; olive flounder, *Paralichthys olivaceus*; ayu, *Plecoglossus altivelis*; snakehead murrel, *Channa striata*; starry flounder, *Platichthys stellatus*; cyprinid, *Cyprinidae* sp.; pike, *Esox lucius*; brown trout, *Salmo trutta*; perch, *Perca fluviatilis*; eel, *Anguilla* sp.; mandarin fish, *Siniperca chuatsi*; Asian swamp eel, *Monopterus albus*; turbot, *Scophthalmus maximus*.

of three recognized viruses; pike fry rhabdovirus (PFRV), grass carp rhabdovirus (GrcRV) and tench rhabdovirus (TenRV). These viruses are confined in their geographical distribution and are generally considered to have less of a disease impact when compared to SVCV.

The perhabdovirus genus has three virus species: *Perch perhabdovirus*, the type species which consists of a single virus member, perch rhabdovirus (PRV); *Anguillid perhabdovirus* which consists of two recognized viruses, eel virus European X (EVEX) and eel virus American (EVA); and *Sea trout perhabdovirus* which consists of two recognized viruses, the lake trout rhabdovirus (LTRV) and the Swedish sea trout virus (SSTV). These viruses are also confined in their geographical distribution, and the evidence that they have a significant disease impact is limited. Beyond the three established genera, several viruses were observed historically in a wide range of fish species and tentatively identified as rhabdoviruses based on the characteristic virion morphology. However, they remained unclassified due to the absence of genetic data, and most of the sample material in these cases has been lost so it is not possible to establish how they relate to the current taxonomy. Other more recently isolated fish rhabdoviruses are currently unassigned because they have not yet been sufficiently well characterized (Table 1).

Virus Structure

Fish rhabdovirus virions have the bullet-shaped morphology that is characteristic of rhabdoviruses in general. Virus particles have a host-derived lipid envelope, and they are sensitive to inactivation by desiccation, as well as heat or UV exposure. Novirhabdovirus virions are approximately 150–190 nm in length and 65–75 nm in diameter (Fig. 2(A)). Sprivirus virions are approximately 120–180 nm in length and 60–90 nm in diameter, and the perhabdovirus virions have a more compact morphology and measure approximately 115–130 nm in length and 85–95 nm in diameter. The unassigned starry flounder rhabdovirus is even more compact, with bullet-shaped virions measuring approximately 100 × 50 nm (Fig. 2(B)). Virions are comprised of five viral proteins. The single glycoprotein (G) on the enveloped surface of the virus particles has been shown to be the major antigenic protein and is by itself capable of eliciting a protective immune response. The matrix protein (M) is an inner component of the virions that binds both the cytoplasmic domain of the G protein

Fig. 2 Electron micrograph showing virions of fish rhabdoviruses. (a) Viral hemorrhagic septicemia virus (VHSV), in the genus *Novirhabdovirus*, (b) Starry flounder rhabdovirus (SFRV), an unassigned rhabdovirus of fish. Photos provided by J.R. Winton.

and the viral nucleocapsid, and it has been shown for IHNV to down-regulate host transcription. The major structural component of the nucleocapsid is the viral nucleocapsid (N) protein that associates with full length viral genomic RNA and facilitates its interaction with the viral polymerase. The large polymerase protein (L) is a complex protein that carries out the enzymatic functions of genome replication and transcription, and the phosphoprotein (P) is an essential co-factor that is required for polymerase function. These five virion proteins are found in all known rhabdoviruses and to date it appears that their roles are conserved across genera. In addition to the five familiar rhabdovirus proteins, the genus-specific hallmark of the novirhabdoviruses is the presence of a sixth protein, the nonvirion (NV) protein, which is not found in virus particles, but it is synthesized, in trace amounts, within infected cells. It has recently been demonstrated that the viral NV protein plays a role in abrogating host innate immune responses and suppressing apoptosis. Through the use of reverse genetics it has been shown that the NV gene and its encoded protein are not essential for replication in cultured cells or in fish, but in most cases it greatly enhances replication and pathogenicity. The absence of an NV gene in the genomes of both the spriviviruses and perhabdoviruses indicates that whatever the role of the NV protein is in novirhabdoviruses, it is not essential for rhabdovirus replication in fish.

Genome

Fish rhabdovirus genomes are single stranded minus-sense RNA molecules of approximately 11,000–11,100 nt for novirhabdoviruses and spriviviruses, or 11,400–11,800 nt for perhabdoviruses. All contain the five canonical rhabdovirus genes in the order 3' N-P-M-G-L 5', and novirhabdovirus genomes have the additional NV gene located between the G and L genes, as illustrated in **Fig. 3**. Genomic termini have leader and trailer regions ranging from 50 to 100 nt for 3' leaders, and 19–115 nt for 5' trailers, and these sequences have inverse complementarity near the genome ends. Untranscribed intergenic regions are generally single nt for novirhabdoviruses, 2 nt for spriviviruses, and more variable for perhabdoviruses. Putative transcription initiation and termination/polyadenylation signals (**Fig. 3**) are conserved across genes within each virus and among viruses within a genus. These signals are identical for spriviviruses and perhabdoviruses but they differ from those of novirhabdoviruses and other rhabdovirus genera. Within genes the untranslated regions upstream and downstream of the open reading frames are variable in length. For example, the putative transcript encoding the G gene of SVCV viruses differs by up to 85 nt due to variation in the 3' untranslated regions of the gene.

Genetic Diversity

Molecular epidemiology and phylogenies have been described at local, regional, and global levels for all major fish rhabdoviruses. Hundreds or in some cases thousands of IHNV, VHSV, and SVCV field isolates have been characterized by genetic sequencing, providing a thorough understanding of the genetic diversity and evolutionary history of these viruses. Genetic typing of IHNV field isolates from North America, Europe, Russia and Asia has shown surprisingly low diversity, with no more than 9% nucleotide divergence globally in a variable region of the G gene. Despite this low diversity, phylogenetic analyses clearly resolve IHNV into five major global genogroups that vary in geographic origin and host specificity. In North America the IHNV genogroups U, L, and M occur in partially sympatric ranges along the Pacific coast, and they show host-specific adaptation and virulence for sockeye salmon (*Oncorhynchus nerka*), Chinook salmon (*O. tshawytscha*), and rainbow trout (*O. mykiss*), respectively. The IHNV J and E genogroups arose in rainbow trout aquaculture in Asia and Europe, respectively, after intercontinental introduction from North America. Genetic typing of global collections of VHSV isolates has revealed greater diversity, with up to 18% nucleotide divergence in full length G gene sequences. Global VHSV phylogenies have 4 major phylogenetic groups designated genotypes I–IV. Genotypes I, II, and III occur in marine waters around Europe, mostly in wild fish, but within genotype I there are major subgroups that contain VHSV isolates from European rainbow trout farms, where they cause a severe disease burden. VHSV isolates in genotype IV are found in North America and Asia, where they cause disease outbreaks in several wild fish species and cultured flounder, but they are not virulent for rainbow trout.

a. Novirhabdovirus

b. Sprivivirus

c. Perhabdovirus

Fig. 3 Genomes of representatives of the three genera of fish rhabdoviruses. All have minus-sense single-stranded RNA genomes of approximately 11,000–11,800 nucleotides (nt) containing nucleocapsid (N), phosphoprotein (P), matrix (M), glycoprotein (G), and polymerase (L) genes as shown. Species in the genus *Novirhabdovirus* have an additional gene encoding a nonvirion (NV) protein at the G-L junction. Approximate sizes (in kDa) of encoded proteins are shown below each gene. Conserved gene junction sequences for each virus are shown in minus-sense (viral RNA) orientation below the genome with arrows indicating putative transcription stop (ending with seven U's) and start signals.

Spriviruses, particularly the SVCV isolates, are well characterized, and partial G gene sequences revealed up to 17.3% nucleotide divergence. Four SVCV genogroups (a-d) have been identified, and the clustering of the genogroups appears closely associated to geographical location, suggesting that the virus has evolved independently in different geographical regions. Genogroup a contains isolates from Asia, and more recently North America and the UK; genogroups b and c contain isolates from Eastern Europe; and genogroup d contains isolates from multiple European countries. To date, the pike fry spriviruses have only been isolated in Europe, where they show relatively high diversity, with up to 28.5% divergence based on partial G gene sequences. The genetic diversity of Perhabdoviruses is less well defined, however, the limited studies have shown that nt diversity within species ranges from 7.9% for *Sea trout perhabdovirus* to 9.3% for *Anguillid perhabdovirus* and 14.2% for *Perch perhabdovirus*.

Global phylogenies of fish rhabdoviruses show clear evidence of diversification into multiple lineages associated with geographic translocations, host jumps and adaptation to different fish hosts, and emergence events. Most recognized host jumps are into cultured rainbow trout, which has occurred multiple times in the histories of both IHNV and VHSV. Viral emergence events often occur after introduction of fish rhabdoviruses into a new geographic range. A classic example is the emergence of SVCV genogroup a in the USA, Canada and the United Kingdom following its potential introduction with infected carp from Asia in the early 1990s. Another example is introduction of VHSV into the Great Lakes region of North America in approximately 2003, resulting in emergence of a new VHSV genotype IVb, that caused large-scale die-offs in many wild fish species for several years. On a practical level molecular epidemiology of fish rhabdoviruses has been useful for fish health management decisions, tracking viral movements, defining viral transmission routes, and supporting risk assessment. Resulting viral phylogenies show clear evidence of anthropogenic influence on directions of virus evolution, with major impacts on fish health and aquaculture world-wide.

Life Cycle

At the cellular level the replication cycle of fish rhabdoviruses is similar to that of rhabdoviruses in other vertebrate hosts. The viral glycoprotein (G) forms trimeric spikes on the virion surface that attach to receptors on fish host cells, facilitating entry by receptor-mediated endocytosis. Fibronectin has been identified as a primary cellular receptor for novirhabdoviruses but the receptor(s) used by most fish rhabdoviruses have not been identified. Once inside the cell the virus is uncoated, releasing the viral nucleocapsid, and the replication cycle occurs in the cytoplasm. Primary transcription of the negative-sense viral genome to produce mRNAs is

accomplished by viral polymerase complexes that contain the viral L, N, and P proteins and are carried in the virus particles. Viral mRNAs are produced in order from the N gene at the 3' end of the genome through the L gene at the 5' end, and translation by host cell machinery generates viral proteins. Based on knowledge from mammalian rhabdovirus systems it is assumed that viral proteins form more polymerase complexes and secondary mRNA transcription produces more viral proteins that accumulate and signal for the polymerase to switch from transcription to replication. Replication creates full-length anti-genomes that serve as templates for progeny RNA genomes. Viral proteins and genomes traffic to the cell surface and assemble, budding through the cell membrane to acquire the viral envelope as new virions are released.

Epidemiology

IHNV, VHSV and SVCV are each currently distributed over several continents in the northern hemisphere, while many other fish rhabdoviruses are distributed more regionally, either in Europe or Asia ([Table 1](#)). IHNV was originally endemic to Western North America before spreading to Asia and Europe in the 1960s and 1980s, respectively. IHNV has a relatively narrow host range, naturally infecting various species of salmon and trout (*Oncorhynchus* sp., *Salmo* sp., *Salvelinus* sp.) and showing variation in host-specific virulence for individual salmonid species. HIRRV also appears to have a narrow host range, causing disease primarily in cultured and wild olive flounder (*Paralichthys olivaceus*) in several Asian countries, but there are rare reports of disease in other species and its host range has not been tested extensively. In contrast, VHSV has an extremely broad host range, naturally infecting over 80 species of fish from diverse taxonomic families. Oceanographic surveys have revealed that VHSV is broadly distributed in numerous species of wild marine fish in the Northern Atlantic and Northern Pacific Oceans, serving as a reservoir that occasionally spills over into cultured fish populations. For VHSV the concept of host specificity generally refers to whether virus strains are of low or high virulence for rainbow trout: VHSV strains from marine fish may cause disease in other host species but they have very low virulence in rainbow trout, while VHSV isolates from trout farms are highly virulent for rainbow trout.

Although the host ranges for the spriviruses and perhabdoviruses are not as great as for VHSV, they are found in a range of fish species including salmonids, cyprinids and percids. Naturally occurring SVCV infections have been recorded predominantly in cyprinid fish and non-cyprinid hosts include sheatfish (*Silurus glanis*), pike (*Esox lucius*), Siberian sturgeon (*Acipenser baerii*), largemouth bass (*Micropterus salmoides*) and bluegill sunfish (*Lepomis macrochirus*), and possibly rainbow trout (*Oncorhynchus mykiss*). The initial identifications were based on serological tests, but subsequent molecular characterization has shown that many of the original carp sprivirus isolates may belong within the pike fry sprivirus rather than carp sprivirus. PFRV was initially reported in pike, sheatfish and grass carp (*Ctenopharyngodon idella*), but given the recent findings, further genetic characterization is required to establish the full host range of the pike fry spriviruses.

PRV, the type species of the perhabdoviruses was first isolated from cultured perch (*Perca fluviatilis*) following mortality events in France and Norway, and antigenically similar viruses were then recovered from diseased pike perch (*Stizostedion stizostedion*), grayling (*Thymallus thymallus*) and largemouth bass (*Micropterus salmoides*) in France and pike in Denmark. SSTV was first discovered in brown trout (*Salmo trutta m. lacustris*) in Finland and sea trout (*Salmo trutta trutta*) from Sweden, but more recently, viruses assigned to the species *Sea trout perhabdovirus* have been isolated from perch, European eel (*Anguilla anguilla*) and brown trout (*Salmo trutta*) in the republic of Ireland. EVA was isolated from American elvers (*Anguilla nostrata*) and EVEX was isolated from European eels.

Both field observations and controlled experimental studies clearly show that transmission of fish rhabdoviruses occurs horizontally by waterborne virus that is shed from infected fish and subsequently infects naive fish without the need for fish contact or vectors. Transmission can also occur vertically from parent to progeny fish by virus associated with the surface of fish eggs or milt. In aquaculture settings disinfection of fish eggs with commercial iodophores is generally effective in preventing vertical transmission. Common routes of virus introduction into fish culture facilities include import of infected fish or eggs, or virus in the water supply due to the presence of wild or feral infected fish in source waters. Within a fish farm or hatchery viruses spread with water flow, feed, or inadequate disinfection of equipment. On a regional scale virus can be spread due to general connectivity and flow of water in aquatic environments, interactions among fish culture facilities, or movement of wild fish populations. On a global scale the history of fish rhabdoviruses includes several examples of intercontinental spread of viruses such as IHNV and SVCV during the mid-1900s, due to movement of contaminated fish eggs or juvenile fish for aquaculture. Among fish that survive virus infection the existence of asymptomatic long-term carriers and reservoirs has been demonstrated in some cases and the biological role of viral persistence is an active area of research.

Clinical Features

The majority of fish rhabdovirus disease outbreaks occur in cultured fish populations, including land-based fish farms, freshwater and marine netpen farms, and conservation hatcheries that rear fish for release into natural environments. In these settings fish infected with rhabdoviruses may exhibit petechial hemorrhages, accumulation of ascites, darkening of body color, or exophthalmia ([Fig. 4](#)), although many fish die without visible clinical signs. Mortality is frequently highest in younger fish and can be explosive in aquaculture settings, resulting in losses approaching 100% in some cases. The impacts of fish diseases include direct loss of fish due to mortality in disease outbreaks, culling of infected fish to avoid spread of disease, and costs of biosecurity

Fig. 4 Clinical signs of disease caused by fish rhabdoviruses. (a) skin hemorrhage in sockeye salmon (*Oncorhynchus nerka*) infected with IHNV (U genogroup strain), (b) exophthalmia (popeye) with eye hemorrhage in rainbow trout (*O. mykiss*) infected with IHNV (M genogroup strain). Photos by G Kurath.

and surveillance programs. Outbreaks of disease due to IHNV, VHSV, and SVCV have also been documented in wild and feral fish populations, with potential impacts on ecosystem health. The significance of fish rhabdovirus disease is evident in the OIE Aquatic Animal Health Code, which includes IHNV, SVCV, and VHSV as three of the 10 globally reportable pathogens of fish. Other fish rhabdoviruses, such as HIRRV, are regionally important pathogens.

Due to the poikilothermic (cold-blooded) nature of their hosts, a unique aspect of fish rhabdoviruses is the strong influence of temperature on virus replication and severity of disease. Fish rhabdoviruses replicate with varying temperature optima typically between 10 and 25°C, and they are inactivated at temperatures well below 37°C. In SVCV infections, clinical disease is usually observed at water temperature between 5°C and 18°C, and is most severe at temperatures below 10°C when it is believed the host's protective immune response is most likely suppressed or delayed.

Pathogenesis and Immune Response

Fish rhabdoviruses gain entry into hosts through the gills and skin. A study using bioluminescence imaging of live fish infected with fluorescent-labeled IHNV indicated the skin at fin bases as a major portal of entry. Inside the host the viruses spread to multiple organs, with hematopoietic tissues of the kidney and spleen as common targets where virus accumulates to high levels. Virus is thought to shed from infected fish in urine, feces, and sloughing of mucus, but this process has not been characterized in detail. The diseases caused by fish rhabdoviruses are generally characterized as acute, hemorrhagic septicemias affecting multiple organs. Death is usually due to organ failure and subsequent loss of osmoregulation. Internally, necrosis of multiple organs is evident upon histological examination.

The immune system of finfish has innate and adaptive immune responses typical of all vertebrates. The response to acute infection with fish rhabdoviruses is a strong interferon-based (IFN) innate response that is rapid and non-specific, resulting in transient cross-protection among different fish rhabdoviruses. It has been hypothesized that fish novirhabdovirus G proteins function as pathogen associated molecular patterns (PAMPs) to trigger signaling that activates the innate IFN response. In many cases this strong innate response is successful in controlling viral infection, leading to survival and clearance of virus. However, in other cases virulent strains of IHNV or VHSV are able to continue replicating despite the innate response, leading to disease and mortality, or viral persistence in some fish. Innate immune evasion mechanisms have been identified in novirhabdoviruses, including host cell shutoff by the viral M protein, and suppression of both the IFN-stimulated gene expression and apoptosis by the NV protein.

Fish that survive rhabdovirus infection typically develop long-term protective immunity. Adaptive immunity in fish includes both humoral and cellular responses. It has been clearly shown that neutralizing antibodies produced in response to the rhabdoviral G protein are necessary and sufficient to provide long-term immunity against fish rhabdoviruses. These antibodies become detectable in fish sera several weeks after infection. Timing of the antibody response is dependent on environmental temperature, generally occurring more rapidly at higher temperatures. There is also evidence of a role for specific cellular immunity, such as cell mediated cytotoxicity, in response to fish rhabdoviruses. Recently new reagents have become available for distinguishing among T cell subsets, which will improve the ability to characterize these cellular immune responses.

Diagnosis

Diagnostic methods for detection and identification of fish rhabdoviruses are well established. Definitive diagnosis of listed pathogens, VHSV, IHNV and SVCV is by isolation of the virus in cell culture followed with confirmation using serological and/or molecular methods. The World Organization for Animal Health (OIE), in its *Manual of Diagnostic Tests for Aquatic Animals*, includes

comprehensive methodology to diagnose and identify all three pathogens see “Relevant Websites section”. Many cell lines from finfish were developed beginning in the 1960s, and they support the replication of a broad range of rhabdoviruses from aquatic animals. Infection of these cell lines produces typical cytopathic effects (CPE) consisting of cell rounding and necrosis following the release of mature virions by budding. The rate of the appearance of CPE is related to the incubation temperature, which is typically set to mirror the temperature optimum of the fish host (e.g., 10–25°C). Cell culture-based assays are also used routinely to detect the presence of infections or to quantify infectious virus. Serological methods using polyclonal or monoclonal antibody reagents have been commonly used for both diagnostics and research, but more recently molecular techniques such as real-time RT-qPCR are often used for surveillance and outbreak tracking, with conventional RT-PCR and sequencing for confirmatory diagnosis or identification of the infectious agent. In many regions of North America, Europe, and Asia cultured fish stocks are routinely surveyed for viral pathogens, including rhabdoviruses, by fish health professionals. For most fish rhabdoviruses surveillance and genotyping data are available as internet-accessible public sequence databases.

Prevention

Control of fish rhabdovirus diseases in aquaculture is based primarily on avoiding infection through biosecurity programs designed to prevent introduction and spread of virus in fish culture facilities. Biosecurity includes strict hygiene practices, use of pathogen-free water sources (such as well water) for early life-stage rearing, application of water treatment technologies for some facilities using water from open sources, and frequent fish health inspections that make use of current technologies. In fish culture settings, the ability to break the cycle of vertical transmission between generations by the disinfection of eggs with an iodine solution has been important in controlling fish rhabdoviruses. Treatment options for fish showing signs of disease are limited to modifying husbandry conditions, typically by reducing fish density, or taking fish off feed to reduce stress. Due to the inadvertent intercontinental spread of several fish rhabdoviruses in the mid-1900s both national and international standards have been established that require fish health inspections for certain fish species that are involved in international or interstate transport. Several fish rhabdoviruses are on the list of pathogens for which inspections are indicated, and the global trade in aquaculture species is reasonably well regulated. However, the huge global trade in ornamental fish is essentially unregulated and is a documented source of virus movement.

Research on vaccines and immunostimulants to protect fish from rhabdovirus infections has been conducted for more than 40 years. Early work focused on traditional vaccination strategies using inactivated viruses or live-modified vaccines, and immunostimulants such as interferon-inducer double-stranded RNA and bacterial lipopolysaccharide. Later, recombinant DNA technology produced experimental vaccines using bacterial or baculovirus expression systems as well as peptide immunogens. However, while some of these traditional and molecular vaccines were reported to be efficacious in laboratory and field trials, prohibitive costs, inconsistent efficacy, licensing barriers, safety concerns, and lack of mass delivery methods for juvenile fish prevented their use on a commercial scale. Since the 1990s, DNA vaccines expressing the viral G gene have been engineered for protecting fish against the novirhabdoviruses, IHNV, VHSV, and HIRRV. These vaccines have been studied extensively and show exceptionally high efficacy against severe viral challenges under a wide range of conditions. Although commercialization of these vaccines faces challenges similar to those noted above, a DNA vaccine against IHNV was licensed in Canada in 2005 for use in Atlantic salmon marine netpen aquaculture. This was one of the first DNA vaccines licensed for use in veterinary medicine and there is currently an industry requirement for 100% vaccination, so the IHNV DNA vaccine is used for millions of fish annually. Interestingly, DNA vaccines for SVCV also provide significant protection, but their efficacy is less than novirhabdovirus DNA vaccines for unknown reasons. In the absence of licensed vaccines for VHSV or SVCV, the national or international legislative controls and sound biosecurity strategies remain the most effective way of preventing the spread of these diseases. Also in the absence of commercially available vaccines some private aquaculture companies may use autogenous vaccines against fish rhabdoviruses, but the extent of this practice is not well documented.

Conclusions

Due to their economic importance, the rhabdoviruses of finfish are among the best studied of all aquatic animal viruses, providing models of how aquatic animal pathogens function, spread, and persist in their environments. Extensive oceanographic surveys have revealed the role of wild fish as important reservoirs of virus for infection of fish in freshwater and marine aquaculture. Conversely, the potential for aquaculture fish to amplify pathogens that may impact wild fish is also a current concern. Field studies are providing insights into the ecology and evolution of fish viral disease, identifying anthropogenic impacts on fish health in altered environments, and supporting development of landscape transmission models for some fish rhabdoviruses.

In laboratory studies fish rhabdoviruses also serve as useful components of model systems to study vertebrate virus disease, epidemiology, and immunology. The availability of a variety of established fish cell lines, the creation of new-generation reagents and tools, and the well-established laboratory challenge models that can use statistically robust numbers of relevant fish hosts make these model systems particularly attractive and powerful. New high throughput sequencing technologies have made the discovery, characterization and classification of viruses a simpler and more rapid process, and consequently the number of recognized rhabdovirus species is likely increase dramatically over the next decade. Experimental infections *in vivo* are increasingly

important for investigating viral pathogenesis, virulence, host-specificity of new emerging viral diseases and assessing the impact of environmental factors, or efficacy of control options such as vaccines. Reverse genetics systems for IHNV, VHSV and SHRV have been used to investigate the roles of individual viral proteins and the genetic determinants of virulence, as well as the use of recombinant viruses as gene vectors or attenuated vaccines. In the area of immunology, quantitative real-time PCR assays, microarray analyzes, and transcriptomics have been used to profile the fish immune gene response following either viral infection or vaccination. Collectively these studies provide essential information for managing fish rhabdoviruses in fish health and contribute to the basic science of virology.

Foot-and-Mouth Disease Viruses (*Picornaviridae*)

David J Rowlands, University of Leeds, Leeds, United Kingdom

© 2021 Elsevier Ltd. All rights reserved.

History

The earliest account that clearly describes foot and mouth disease was made by Fracastorius in 1546. Today, FMD is still one of the most important diseases of domestic livestock.

It was the first animal disease shown to be caused by a filterable agent in 1897 by Loeffler and Frosch, who also demonstrated the presence of neutralizing antibody in serum. It is also the first virus for which serotype differences were recognized. Further milestones were the demonstration by Waldmann and Pope in 1921 that guinea-pigs could be infected by the virus and by Skinner in 1951 that it caused a lethal infection in suckling mice, thus providing small animal models for FMD research. Subsequently, cultivation of FMDV in tissue culture cells has enabled studies of viral structure and replication and also the large-scale production of vaccines. The combination of strict control measures and the use of vaccines has led to elimination of the disease from some parts of the world but many regions remain endemic for FMD.

Classification

FMDVs comprise a species within the *Aphthovirus* genus of the *Picornaviridae*. The nature and organization of the genome, mode of replication and structure of the virion are, in general, similar to other viruses in the family. The original subdivision of the *Picornaviridae* into the four genera, *Enteroviruses*, *Rhinoviruses*, *Cardioviruses* and *Aphthoviruses* was based on physicochemical properties such as susceptibility to acid inactivation, buoyant density of CsCl solution and the nucleotide composition. Analysis of evolutionary relationships by nucleotide sequence comparisons have partly endorsed the original classifications; however, with further virus discovery the family has now expanded greatly and currently includes 110 species which are classified into 47 genera.

The genus aphthovirus originally comprised the seven serotypes of FMDV (Fig. 1) With the discovery of more related viruses the genus was expanded to include 4 species; FMDV, bovine rhinoviruses A and B and equine rhinovirus A (Fig. 2). A combination of properties which distinguish the FMDVs include: (1) extreme sensitivity of the virion to acid inactivation (< pH 6.8 in low ionic strength buffer); (2) high buoyant density in CsCl (1.43–1.50 g cm⁻³); (3) an exceptionally long multi-domain untranslated region (UTR) at the 5' end of the genomic RNA, including a large poly C tract (a property shared with some cardioviruses); (4) three separately encoded VPg proteins; (5) the use of two alternative in-frame protein translation initiation sites; (6) a leader protease protein located in the N-terminal region of the polyprotein; (7) interruption of translation (ribosome skipping) to facilitate polyprotein processing and; (8) very rapid replication.

Virion Structure

As for other picornaviruses, FMDV particles are non-enveloped icosahedrons comprising 60 copies each of four structural proteins, VP1–4, encapsidating a single copy of the single-stranded positive-sense genomic RNA. Determination of the structure of the virus by X ray crystallography and cryo electron microscopy (Fig. 3) has shown that the three larger proteins (VP1–3) have the eight-stranded antiparallel β -barrel folding motif seen in other picornaviruses and some plant viruses. VP4 is located on the inner surface of the particle. In common with other picornaviruses, VP1 molecules are disposed around the axis of five-fold symmetry whereas VP2 and VP3 alternate around the two- and three-fold symmetry axes. In contrast to many other picornaviruses, such as enteroviruses, in which the virion remains intact as an empty particle following thermally induced release of the RNA, heat or acid degradation of FMDV particles results in dissociation into pentameric subunits, consisting of five copies each of VP1–3, with release of the RNA and VP4. Several features of the structure are peculiar to FMDV. The protein shell is generally thinner and the external surface is smoother than in other picornaviruses. This is a result of the smaller sizes of VP1–3 (VP1 213, VP2 218, VP3 220 amino acids for virus O1) compared to other picornaviruses. The truncations are in the loop regions linking the core elements of the β barrels, which in other picornaviruses form prominent features at the outer surface. The deep grooves or pits encircling the five-fold axes of many picornaviruses are not present in FMDV and the position equivalent to these invaginations is occupied by the C-terminal portion of VP1. An important exception to the generally smooth contours of the surface of FMDV is provided by the G-H loop of VP1 (Fig. 3). In serotype O viruses this large loop extends from residue c.130 to 160 of which c. 135–158 are too disordered to be visible in electron density maps. The length of the VP1 G-H loop differs between different serotypes of the virus. In serotype O1 viruses the disorder of the VP1 G-H loop is induced by a disulfide bond between the cystine residues VP2 130 and VP1 134. Under reducing conditions this bond is broken and the G-H loop collapses onto the surface of the virus in an ordered configuration. In all serotypes the VP1 G-H loop includes an immunodominant antigenic site to which a high proportion of virus neutralizing antibodies are directed. Synthetic peptides representing sequences from this region are immunogenic and can induce

protective immunity. The sequence of this region is variable both in composition and length between different viruses with the exception of a highly conserved receptor-binding motif which includes the triplet, Arg, Gly, Asp.

Genome

The genome consists of a single molecule of single-stranded positive-sense RNA, which is infectious if transfected directly into cells in the absence of the protein components of the virion. The genome is longer than for most picornaviruses, comprising approximately 8500 nucleotides. The order of the gene products on the genome is basically similar to other picornaviruses but there are some unique/unusual features (Fig. 4). The genomic RNA terminates at the 5' untranslated end with a small protein, VPg

Structure of the 5' end of FMDV RNA

Fig. 5 Secondary structure prediction for the 5'UTR of FMDV RNA with major functional motifs individually labeled.

(or 3B), linked by a phosphodiester bond through a Tyr at position 3 to the terminal uridine residue of the RNA genome. There is a variable length of poly(A) tract at the 3' end. Uniquely, the FMDV genome encodes three distinct VPgs, which are used with equal efficiency. This is a consistent feature of all FMDVs isolated to date (except for one which has only two copies of VPg) but the rationale for this gene triplication is unknown. In fact, virus derived from infectious cDNA clones from which one or two of the VPg copies are deleted is still infectious, although RNA synthesis is slower and viruses with reduced numbers of copies of VPg may have a competitive growth disadvantage. The 5' untranslated region (UTR) is exceptionally long (c. 1300 nucleotides) even by picornavirus standards and includes at least five distinct structural motifs (Fig. 5).

The 5' end of the genome has a ~400 nucleotide sequence, known as the S fragment, which is predicted to fold into an almost complete hairpin. Its function is unknown but by analogy to the highly structured 5' sequence of poliovirus RNA it is likely to be involved in the control of RNA replication. Deletion experiments have shown that viable virus can be recovered in cultured cells (BHK-21) from genomes in which a large proportion of the predicted hairpin structure has been removed. However, truncation of the S fragment alters the host susceptibility profile and there is evidence that it interacts with cellular proteins in a species-specific manner to down-regulate innate immune response mechanisms.

The S fragment is followed by a poly(C) tract of 100–200 residues (exceptionally in excess of 400), depending on virus isolate. This tract is composed almost entirely of cytidine residues, occasionally interrupted with uridines. The function of the poly(C) tract is unknown and its presence in other aphthoviruses is equivocal. Its importance can be implied from its presence in all virus isolates and the observation that truncated poly(C) tracts increase in length following serial cell passage in cells. There is some evidence from FMDV and Mengovirus (a cardiovirus) that the length of poly(C) is related to pathogenicity. For example, deletion of the poly(C) tract from the highly virulent Mengovirus renders it completely non-pathogenic in mice.

To the 3' side of the poly(C) tract there is a variable number of repeat domains, which are predicted to fold as pseudoknot structures. The number of pseudoknots varies between different virus isolates but none has been isolated with fewer than two copies. The number of nucleotides involved in these deletions/insertions corresponds closely to the number of nucleotides required to form the predicted pseudoknot structures, providing circumstantial evidence for their structural integrity. Although the role of the pseudoknots is unclear their evolutionary retention suggests that they provide the virus with a competitive advantage.

To the 3' side of the pseudoknots there is a stem-loop structure known as the *cre* element (cis active replication element). This acts as a template for the uridylation of the VPg protein by 3D^{pol}, the viral RNA dependent RNA polymerase, in the replication complex. The uridylated VPg then functions as a primer for RNA replication. Although *cre* elements are found generally in picornaviruses, they are frequently present within the protein coding sequence and location within the 5' UTR is peculiar to FMDV.

The 3' 435 nucleotides of the 5' UTR fold into a series of stem loop structures similar to those present in the equivalent region of cardiovirus 5' UTRs and function as an internal ribosome entry site (IRES) to initiate protein synthesis. There is a short pyrimidine-rich tract between the IRES and the first of two in-frame alternative translation initiation codons.

The 3' UTR is approximately 100 nucleotides in length and includes two stem-loop structures (SL1 and SL2) which make important interactions with features in the 5' UTR to facilitate translation and RNA replication. It terminates in a poly(A) tract of variable length. Bioinformatic analysis of FMDV genome sequences has revealed an underlying feature termed GORS (genome ordered RNA structure) not seen in other picornaviruses, such as enteroviruses. It is speculated that this inherent structural feature results in the production of short double stranded RNA products following genome degradation, which may be inhibitory to innate immune mechanisms. The high GORS score may contribute to the ability of FMDV to establish persistent infections and it is also a feature of hepatitis C virus which regularly induces chronic infections.

Protein Products

The protein-coding region is a continuous open reading frame of 6999 or 6915 nucleotides for FMDV serotype A¹⁰, depending on which of two functional in-frame initiation codons is used. The order of the gene products is shown in [Fig. 4](#).

Leader protein

The leader protein L^{pro}, which precedes the structural proteins, is a papain-like cysteine protease which cleaves the polyprotein at the L-P1 junction. It also cleaves a number of host proteins with profound consequences for protein translation (see "Section Translation") and innate immune functions. L^{pro} invariably occurs as two forms, L_{ab} and L_b, which are translated from different in-frame initiation sites separated by 84 nucleotides. Both forms of the protein are equally active proteolytically and the reasons for the conservation of two initiation sites and hence the expression of two forms of the protein are still unclear. The proportion of L_b produced exceeds that of L_{ab} due to a less efficient L_{ab} translation initiation site and the presence of low abundance codons in the L_{ab} – L_b region. The L^{pro} proteins are not essential for virus viability per se since virus derived from an infectious clone with deleted L^{pro} domain can replicate. However, it has an attenuated phenotype and has been proposed as a candidate live vaccine.

P1 region

The P1 region consists of the structural proteins. P1A, B, C and D are equivalent to VP4, 2, 3 and 1 respectively. The precursor protein P1 is cleaved by the viral protease 3C^{pro} into VP0 (VP4 + VP2), VP3 and VP1 which together comprise the monomeric structural subunit. Five monomers assemble to form a pentameric subunit, which is the building block for icosahedral virion assembly. Cleavage of VP0 into VP4 + VP2 is a final assembly maturation step and the mechanism is unclear.

P2 region

The P2A protein is vestigial in size compared to other picornaviruses, being only 18 amino acids long, but it enables the nascent separation of the polyprotein at the P2A-2B junction. The amino acid sequence of 2A facilitates termination of translation of the polyprotein at this point without dissociation of the translation complex from the ribosome. Translation then continues but without the formation of a peptide bond between 2A and 2B. Cellular release factors determine the efficiency of this process and it is proposed that changes in the levels of these during infection can alter the relative amounts of structural and non-structural proteins produced. There is some direct evidence for this in Theiler's virus – a cardiovirus – which adopts a similar mechanism of interrupted translation. The rationale for such a mechanism is that it provides for the differential production of structural and non-structural proteins as requirements change during the replication cycle. 2B multimerizes to form an ion channel (viroporin) and can alter the distribution of ions across cellular membranes. It antagonizes components of the cellular innate immune mechanisms. The precursor protein 2 BC influences membrane trafficking in infected cells, inhibiting transport from the ER to the Golgi complex. P2C has a nucleoside triphosphate binding motif and has ATPase activity. It appears to have a role in RNA replication since mutations in this protein can relieve the inhibition of RNA synthesis seen in the presence of guanidine hydrochloride. It forms hexameric complexes and is thought to function as an RNA helicase during viral replication.

P3 region

The role of P3A in FMDV is unclear but it does not seem to alter cellular membrane architecture like 3A protein of poliovirus. The N terminal portion of the protein is conserved and includes both hydrophilic and hydrophobic domains through which it associates with membranes, where it functions as an important component of the RNA replication complex. The C terminal portion is variable between virus isolates and has an important influence on host specificity. Viruses with a significant deletion in 3A are highly pathogenic for pigs but are much attenuated in cattle. P3B or VPg occurs as three tandem copies of 23, 24 and 24 amino acids. Although differing in sequence each is rich in Pro, Arg and Lys residues and has a single Tyr at position three. Each of the individual VPg molecules is highly conserved between the A, O and C serotype viruses. The VPg molecules are post translationally modified to function as primers in RNA synthesis. All encapsidated RNA molecules terminate with a VPg molecule and each of the three forms is found in equal abundance in encapsidated viral RNA. Actively translating viral RNA lacks VPg, and cell extracts contain an enzyme that cleaves the phosphodiester bond to produce RNA terminating with a 5'-monophosphate. For poliovirus the cellular enzyme responsible for the removal of VPg has been identified as 5' tyrosyl-DNA phosphodiesterase 2 (TDP2) and this is likely to be also the case for FMDV. The observation that all virion associated RNA terminates in VPg suggests that it has a role in the selection of molecules for encapsidation.

P3C^{pro} is the protease responsible for the majority of the processing cleavages. In common with other picornaviruses, sequence analysis suggests that the catalytic site of 3C^{pro} is related to trypsin, a serine protease, but with the replacement of the nucleophilic serine residue with cysteine.

P3D^{pol} is the RNA-dependent RNA polymerase responsible for RNA replication and VPg uridylation. The crystal structure has been solved in the apo form and in complex with primer and template. As has been demonstrated for poliovirus, FMDV 3D^{pol} can form fibrillar structure in vitro but the significance of these in RNA replication is unknown.

P3CD precursor has a distinct function as a catalyst for the 3D^{pol} mediated uridylation of VPg. A range of precursor proteins derived from the P3 region is present in infected cells resulting from the dynamics and ordering of the proteolytic processing cascade. It is likely that some of these intermediate products have distinct roles in the replication process.

The molecular structures of virus particles, L^{pro}, 3C^{pro} and 3D^{pol} have all been determined by X ray crystallography.

Life Cycle

Cell Attachment and Entry

The large mobile G-H loop of VP1 located at the surface of FMDV particles mediates their binding to susceptible cells. The sequence of the loop contains a highly conserved motif, Arg, Gly, Asp, which is a hallmark of ligands for a number of heterodimeric cell surface molecules called integrins. Synthetic peptides including this sequence can compete with virus for cell attachment and treatment of the virus with proteolytic enzymes such as trypsin, which cleave within the G-H loop, also prevents virus binding. Although the virus can bind to a number of integrins there is good evidence that $\alpha_v\beta_6$ is the preferred receptor *in vivo*. The structure of a complex of $\alpha_v\beta_6$ bound to FMDV has been determined by cryo electron microscopy (Fig. 3).

Following attachment, the virus is internalized by endocytosis and release of the RNA is triggered by acidification in early endosomes. Reduction of the pH below c. 6.8 seems to be all that is required to initiate the infection process and the mechanism by which the genome is delivered to the cytoplasm is unknown. It is unlikely that cell entry requires complete dissociation of virions into pentameric subunits and genomic RNA triggered by acidification of the endosome since this would expose the RNA to the potentially hostile environment within the lumen. Transient empty particles are produced from aphthovirus particles under some conditions and these may represent intermediate structures that protect the genome during entry into the cytoplasm. Many tissue culture adapted strains of the virus have evolved *in vitro* to use heparin sulfate at cell surface as an alternative receptor.

RNA Replication

RNA of infecting virus functions as a template for the synthesis of a negative-sense complementary strand, which serves as template for the synthesis of positive-sense strands, identical to the original infecting molecule. Positive-strands are synthesized in a complex structure [replicative intermediate (RI)] consisting of a single negative-strand template and several (c.6) nascent positive-strands. RNA synthesis is asymmetrical in favor of positive-strands. A proportion of the negative-strand templates occur as full-length double-stranded hybrids [replicative form (RF)] and appear to take no further part in RNA synthesis. RF molecules accumulate in the cell during viral replication. Each RNA replication event is initiated by priming with an uridylated VPg molecule.

A single molecule of viral RNA is sufficient to initiate infection, which implies that it can function sequentially as a template for translation, to produce the polymerase enzyme(s), and as a template for RNA replication. Single-stranded viral RNA is infectious in the presence of inhibitors of host cell DNA-dependent RNA polymerase. Double-stranded viral RNA is also infectious but not in the presence of inhibitors of the cellular polymerases.

As for other positive sense RNA viruses, the RdRp of FMDV is error prone due to the absence of a proof-reading capability. Consequently, point mutations occur at a high rate and the viral population exists as a quasi-species – a swarm of variant molecules the sequence of which represents a consensus. In addition to a high replication error rate, recombination occurs readily. Both of these features contribute to the genetic flexibility of FMDV and enable it to respond rapidly to environmental selective pressures.

Translation

FMDV RNA is translated efficiently in a cell-free system (e.g., rabbit reticulocyte lysate) to produce protein products similar to those found in infected cells. The 435 nucleotides upstream of the first AUG initiation codon is folded into a complex structure similar to that of the equivalent region of cardiovirus RNAs. This sequence acts as an IRES, allowing initiation of translation in the absence of the host cell CAP-binding protein, eIF4E. In addition to canonical translation initiation factors, IRESs recruit a number of cellular IRES trans-activating factors (ITAFs) which appear to act as chaperones to facilitate optimal conformational folding of the IRES sequence. The rate of total protein synthesis in virus-infected cells does not change until its decline towards the end of the growth cycle, when cytopathic effects (CPE) are apparent. There is, however, a marked change in the profile of proteins produced. When viral replication is maximal, virtually no host cell proteins are produced. This “swap over” of translation from host to viral products is similar to the situation in cardiovirus-infected cells and differs from the kinetics of translation following infection of cells with enteroviruses. In the latter, infection results in a rapid shutdown of host cell protein translation, which is followed later by a resumption of protein synthesis due to the increasing production of viral proteins. The shutdown induced by enteroviruses is largely, if not entirely, due to virus-induced cleavage of a host protein, p220 or eIF4G, an important component of the CAP-binding complex required for the initiation of translation of host mRNAs. In these viruses, eIF4G is cleaved by P2A^{Pro}. Cardioviruses do not induce eIF4G cleavage but downregulate host mRNA translation via P2A induced hypophosphorylation of initiation factor 4E-BP1 and so out-compete host mRNAs for utilization of the translation machinery. Although the kinetics of protein translation in FMDV-infected cells resemble those of cardiovirus-infected cells, eIF4G is cleaved. In contrast to enteroviruses, in FMDV eIF4G is cleaved by L^{Pro} and not by P2A^{Pro}. 3C^{Pro} can also cleave eIF4G but at a different site from L^{Pro} and later in the infection cycle. Inhibition of host cell protein synthesis is likely to be of advantage to the virus both by removing competition for access to the translation machinery and also by inhibiting the expression of innate immunity response genes in infected cells. FMDV from which L^{Pro} is deleted has a reduced ability to inhibit the interferon system.

Post-Translation Processing

The polyprotein translation product of FMDV RNA is proteolytically processed by three of four virus-encoded enzyme activities (Fig. 2). Three of the cleavages occur nascently on the growing polypeptide chain. The first separates L^{pro} from P1, the structural protein precursor, and is carried out by L^{pro} itself. The cleavage is within a Lys-Gly dipeptide and probably occurs normally in *cis* but can also occur in *trans*. L-P1 cleavage is the only processing step which is inhibited by the tripeptide D-Val-Phe-Lys-CH₂Cl. Both Lb and Lab are proteolytically active.

The second primary “cleavage” occurs at the junction of P2A and P2B and is facilitated by the 18-amino acid P2A sequence. There is good evidence that the separation of 2A from 2B and the remainder of the polyprotein does not occur by proteolytic hydrolysis of a peptide bond but rather involves a novel process of interrupted translation, referred to as ribosomal skipping.

The third primary cleavage is between P2C and P3A and is catalyzed by 3C^{pro}. This protease is responsible for all other processing cleavages, apart from that which generates VP2 (P1B) and VP4 (P1A) from the precursor VP0 (P1AB). Many cleavages catalyzed by 3C^{pro} occur at Glu-Gly junctions but other dipeptides are recognized and 3C^{pro} of FMDV is the most promiscuous of the picornavirus proteases. The cleavage event to produce VP2 and 4 from the precursor, VP0, occurs in the final stages of virus maturation. The mechanism of this cleavage is not known.

The production of viral proteins via cleavage from a polyprotein allows for alternative cleavage pathways and provides a range of intermediate precursor proteins. It is thought that some of the intermediate products have roles additional to those of the mature cleavage products, thereby expanding the functional capacity of a small viral genome.

Virus Assembly and Release

A variety of assembly intermediates containing equimolar amounts of VP1, 2 and 0 are detected in infected cells. These correspond to monomer and pentamer subunits of the icosahedral capsid and 75S empty particles, which lack viral RNA but possess antigenic properties similar to mature viral particles. Following pulse-labeling experiments, empty particles can be “chased” into viral particles, but it has not been shown that they are on the direct morphogenetic pathway. All encapsidated RNA terminates with VPg, suggesting that this plays a role in selection for packaging and/or that only nascent RNA is encapsidated before VPg is cleaved off by TDP2. There is also evidence for the presence of multiple short RNA sequence motifs (packaging signals) distributed through the genome, which facilitate virion assembly.

Paracrystalline arrays of virus are visible in infected cells and are released by lysis of the cell. In addition there is evidence that some viral particles are secreted prior to cell disruption or are released within exosomes.

Epidemiology

FMD occurs widely and is endemic in many countries, especially in tropical regions. Many regions, including Europe, North America, Australia and New Zealand are free of the disease and maintain this status by rigorous application of import controls and quarantine. Mass vaccination campaigns have eliminated the virus from some areas, e.g., Europe, but have been less effective in others, due largely to logistical problems of vaccine distribution and the techniques of animal husbandry employed. The global distribution of the serotypes is shown in Figs. 6 and 7. There have been no reports of isolation of viruses belonging to serotype C since 2004 and these appear to now be extinct.

In regions endemic for FMD, the virus is most likely maintained in persistently infected animals. It has been shown experimentally that infected bovines can secrete virus for long periods after the initial episode of disease. In some areas the wild animal population may act as a reservoir for infection (e.g., Cape buffalo in Africa). In non-endemic areas infection may be introduced from a variety of sources such as the importation of infected livestock, contaminated animal products such as carcasses containing bone (in contrast to meat, the post-mortem acidification of bone marrow and other non-muscular tissues is insufficient to inactivate the virus), or contaminated materials. More locally, transmission of infection is by direct transport of contaminated animals or materials or by wind-borne carriage of infectious aerosols. It is also suspected that the virus can be passively transmitted by migrating birds. High-throughput deep sequencing methodologies now allow virus transmission to be traced forensically at high resolution.

Host Range

The virus typically infects cloven-hoofed species with domestic cattle being the most susceptible. Domestic pigs are also important hosts and are particularly effective in propagating the disease, since they secrete large quantities of virus in the form of aerosols. In sheep and goats, the clinical manifestations of infection are usually less severe than those seen in cattle and pigs making initial symptomatic diagnosis in these species more difficult. Natural infection of Indian elephants and of camels has been reported. Many wild species of deer and antelope are susceptible to infection and in African Cape buffalo infection is asymptomatic. Persistent infection with prolonged shedding of virus for months or years has been reported in wild and domestic bovine species. Although direct transmission of infection from carrier animals to naive animals has proven difficult under laboratory conditions

Fig. 6 Global distribution of FMDV serotypes O, A, C and Asia 1 between 2009 and 2018. (the FAO World Reference Laboratory for FMD and the OIE/FAO Reference Laboratory Network).

Fig. 7 Distribution of FMDV serotypes SAT 1, SAT 2 and SAT 3 between 2009 and 2018. (the FAO World Reference Laboratory for FMD and the OIE/FAO Reference Laboratory Network).

there is epidemiological and some experimental data which supports the importance of persistent infection in maintenance and transmission of disease in the wild. A wide range of animals, including Australian marsupials and even birds, have been infected under laboratory conditions and, very rarely, infection of man has been demonstrated.

The most important small animals for laboratory investigations are the guinea-pig and the suckling mouse. In the former, injection of virus intradermally into plantar pads results in the formation of vesicular lesions both at the site of injection and in the mouth and the remaining feet, and so resembles the lesion distribution in naturally infected susceptible species. Intra-peritoneal infection of suckling mice results in rapid death. The viruses can be propagated in primary cells and cell lines of bovine or porcine origin. Cells derived from the BHK-21 line are most widely used for research or vaccine production purposes. The virus can be titrated by plaque assay in cultured cell monolayers or by cytopathic end-point dilution assay in microtiter plates. Primary bovine cells (e.g., bovine thyroid cells) are used for field virus isolation, as they are more susceptible to non-culture adapted virus strains.

Genetics and Evolution

In common with other RNA viruses, the mutation rate of FMDV is extremely high and virus populations exist as quasispecies in which each individual genome is likely to differ from every other. Antigenic sites on the viral particle are tolerant of sequence variation, and antigenic diversity is a significant property of the virus.

In addition to evolution by the accumulation of point mutation, genomic recombination occurs at a high rate in vitro and comparative sequencing of field isolates suggests that it is also a frequent event in vivo. The frequency and genomic location of recombinatorial events mirrors the genetic relatedness of the parental viruses.

Serological Relationships and Variability

Seven serotypes of FMDV are recognized, the definition of serotypes being that an animal convalescent from infection by virus of one serotype is fully susceptible to viruses of any of the remaining six. In addition to the major serotype differences, there is considerable antigenic variation between viruses within serotypes. The serological relationships between FMDV isolates are paralleled by genetic relationships as evidenced by RNA sequence analyses (Fig. 1). Major advances in nucleotide sequencing technologies in recent years have resulted in these becoming the most accurate and rapid methods for evolutionary and epidemiological studies.

For epidemiological studies and vaccine strain selection the serological relationships between field virus isolates or laboratory strains are expressed as r values, i.e., the ratio of the neutralizing titers of immune sera against heterologous and homologous viruses. The serological relationships between virus isolates are frequently nonreciprocal, showing that closely related viruses may induce broadly cross-reactive or narrowly specific immune responses.

Pathogenesis and Clinical Features

The principal route of infection appears to be via aerosol impinging on the pharynx and respiratory tract. Aerosols may be produced locally during feeding on contaminated foodstuff or may be transmitted over considerable distances under appropriate meteorological conditions. Pigs secrete particularly high levels of virus-contaminated aerosols. In addition to mucosal secretion, high levels of virus are found in milk. Pasture may be contaminated with virus from urine and feces. Although the virus is labile when purified in laboratory conditions it can survive for long periods in certain environments (e.g., in slurry) at low temperatures.

Vesicular lesions appear in the mouth on the tongue, gums and cheeks and later on interdigital mucosa and coronary bands of the feet. Virus can be isolated from many tissues in the body. The onset of clinical disease is usually very rapid and lesions can develop as early as 1–2 days after infection, depending on the virus strain and level of exposure.

The pathogenicity of FMDV varies according to the virus strain, host species and age. The factors that govern the virulence of FMDVs are poorly understood and as with most viruses are probably multifactorial. Domestic cattle are the most susceptible species and morbidity is usually c. 100% in non-vaccinated animals. Wild bovines, such as African Cape buffalo, may produce no clinical manifestations. Although the disease is rarely fatal in adult domestic animals (< 5%), significant mortality may occur in young animals (c. 50%). Overt symptoms of disease are less obvious in pigs, although this species produces large volumes of infectious aerosol and are very important in disease transmission. Symptoms are much less severe in ovine species and can be unapparent, which can complicate surveillance for the presence of FMD.

Infection of bovines typically produces a rapidly progressing febrile illness and the development of massive vesicular lesions in the mouth and on the feet. Infection primarily involves mucosal epithelia in the oropharynx, which correlates with expression of the principle receptor, integrin $\alpha_v\beta_6$. The lesions rupture with considerable loss of epithelial tissue (Fig. 8). The resulting discomfort discourages feeding until the lesions heal by the infiltration of fibrous tissue. The severity of the disease results in long-term loss of productivity in terms of meat and milk yield, and lameness may be a serious consequence for draft animals. Abortion and chronic subfertility are also common. Other organs infected include mammary glands, pancreas and heart.

Immune Response

Infection elicits a vigorous humoral antibody response and, after recovery, immunity to re-infection with viruses of the same serotype is prolonged. The humoral antibody response is induced by both T-cell independent and T-cell dependent mechanisms. The role of cytotoxic T cells in recovery is unclear.

Fig. 8 Severe symptoms of FMD showing extensive sloughing of lingual epithelium.

Four antigenic sites recognized by antibodies capable of neutralizing the virus have been described. One of these is an immunodominant linear sequence comprising the G-H loop of VP1, and synthetic peptides representing this tract are effective in inducing high levels of virus neutralizing antibody and can protect animals from infection. The remaining antigenic sites are conformational and one spans the interface between protomers in the assembled particles and so is lost on particle dis-assembly.

Antibody responses to several of the non-structural proteins are induced during infection and these are being developed as markers to distinguish vaccinated from infected animals.

Diagnosis

Initial diagnosis in the field is based on clinical observations, which are usually obvious for cattle but less so for other species, especially sheep. The presence of FMDV must then be confirmed using more specific virological and/or serological methods. Cultivation of virus from clinical samples is the gold standard for confirmation but this may be complicated by lack of containment facilities to perform the isolation, difficulties in growing field virus strains in culture cells and poor quality of samples. It is also a lengthy process. Virus antigens can be detected using antibody based assays such as enzyme-linked immunosorbent assay (ELISA) using polyclonal sera or monoclonal antibodies. Genome sequence based methods relying on the reverse transcriptase – polymerase chain reaction (RT PCR) are used increasingly for diagnosis and for high accuracy epidemiological studies. Modern diagnostic techniques are becoming ever more sophisticated through the development of “pen side” rapid lateral flow devices, analogous to those used in pregnancy testing kits, and portable automated RT PCR apparatus.

Prevention and Control

In disease free regions, natural protection afforded by geographical barriers is rigorously reinforced by strict controls on the importation of susceptible animals and potentially contaminated materials. Where outbreaks occur sporadically, due to occasional introduction from external sources, embargoes on animal movement and slaughter of infected herds have been successful in maintaining a disease-free national herd. In endemic areas, control is by mass vaccination. Ring or barrier vaccination is also used to limit the spread of infection during outbreaks.

Dramatic demonstrations of the vulnerability of naive livestock to large-scale epidemics of FMD were provided by the outbreaks of serotype O virus in the UK and of serotype A virus in South America in 2001. The outbreak in the UK resulted in the slaughter of over 10 million animals (most of which were uninfected) to control spread of the disease and the cost to the country was many billions of pounds. In South America the outbreak was controlled by the resumption of blanket vaccination of all livestock.

The first vaccines against FMD were produced by formalin inactivation of lymph drawn from lesions on the tongues of infected cattle. This source of immunizing virus was replaced by the Frenkel method of culture in fragments of epithelium stripped from the tongues of slaughtered cattle. Most vaccine in use today is produced by growing the virus in suspensions of BHK-21 cells in fermentation vessels of up to 10,000 liters capacity. Approximately 2×10^9 monovalent doses of vaccine are administered annually. Aziridines have largely replaced formalin as the inactivant, since the inactivation kinetics of the latter are non-linear and residual live virus in vaccines has occasionally been the source of outbreaks of disease. The serotype and strain composition of vaccines have to be tailored for local requirements. Inactivated virus is usually adjuvanted by adsorption onto aluminum hydroxide gel, and saponin may be added to enhance potency. In pigs, such vaccines elicit only immunoglobulin M responses and for this species vaccines are formulated with oil adjuvants. Oil adjuvanted vaccines are widely used for all species in S. America and China.

Solid protection requires high levels of neutralizing antibodies and to achieve this with inactivated vaccines, immunization is repeated two to three times a year. The development of live attenuated vaccines has not progressed due mainly to the complexity of antigenic diversity and the fear of reversion to a virulent phenotype. However, greater understanding of the structure and function of the virus provides the basis for development of rationally designed live vaccines which may overcome the disadvantages inherent in earlier attempt to derive attenuated vaccine strains.

Future Perspectives

There is great scope for developments in FMD vaccines to improve safety, stability, cross-protective efficacy and duration of immunity. Experimental peptide vaccines were demonstrated to elicit protective levels of neutralizing antibodies more than 30 years ago but poor responses in target species as compared to small animal models curtailed their development. However, research continues in this field. Production of virus-like particles (VLPs) via the co-expression of the structural precursor protein, P1, together with the protease, 3C^{pro} in recombinant expression systems, such as baculovirus transduced insect cells, is developing rapidly. The inherent instability of FMDV VLPs is being addressed by the identification and inclusion of stabilizing mutations. Adenovirus vectored P1/3C^{pro} constructs are being investigated as live recombinant delivery systems and naked DNA constructs capable of expressing the same proteins have also been shown to elicit anti FMDV responses. In addition, despite the failure

through reversion to virulence of attenuated vaccines developed many decades ago, increased understanding of the structure and function of the viral genome at the molecular scale is leading to the development of rationally designed attenuated vaccine strains (virtually) incapable of reverting to a virulent phenotype. Massive outbreaks of FMD in the UK and in South America in 2001 stimulated interest in the development of drugs to halt the rapid spread of infection. Improved rapid diagnostic methods are being explored as is the ability to accurately distinguish infected from vaccinated animals.

As to the molecular properties of the virus, both the determination of the near atomic structure of the particle and several of the non-structural proteins and the cloning and manipulation of full-length infectious cDNA molecules are important steps towards understanding the unique features of the virus.

Glossary

Borell bodies Virus-containing granules that cluster to form “Bollinger bodies” and are found in cells infected with FWPV.

Inclusion bodies (Or elementary bodies) are nuclear or cytoplasmic aggregates of stable substances, usually proteins.

Passerine A perching bird of the order Passeriformes.

Photolyase Enzymes that repair DNA damage caused by exposure to ultraviolet light.

Psittacine A bird of the parrot family.

Scab Skin lesion.

Viroplasm (Or virus factories) cytoplasmic inclusion body where viral replication and assembly occurs.

Introduction

Avipoxviruses (APV), of which fowlpox virus (FWPV) is the prototypic member, have received considerable attention due to their devastating effects to populations of domesticated, pet and wild birds, and due to their narrow host range, which allows them to be used as safe, non-replicating vectors for vaccination of birds and mammals. Despite their impact and increased frequency in wild birds, our understanding of the APV molecular and biological characteristics is restricted to FWPV and canarypox virus. Only few APV genomes are currently available and the viruses’ global distribution, phylogenetics and epidemiology are not as well understood as those of *Orthopoxviruses*.

Classification

Avian pox viruses or avipox viruses (APV) form one genus of the Chordopoxvirinae subfamily. APV infect and cause diseases specifically in birds and have been isolated from more than 230 avian species worldwide. Traditionally, avipoxviruses have been assigned to species on the basis of original host, growth and morphological characteristics in the chorioallantoic membranes of embryonated eggs or cell cultures, and/or on the basis of clinical manifestations. Moreover, restriction enzyme and single-gene PCR (e.g., *P4b* gene) analyses have been used to detect and differentiate APV. Genome DNA sequencing has confirmed most provisional species demarcations, although some strains are now regarded as variants of other APV. According to the ICTV, ten APV species have so far been identified and classified. These include *Fowlpox virus* (FWPV), *Canarypox virus* (CNPV), *Juncopox virus* (JNPV), *Mynahpox virus* (MYPV), *Pigeonpox virus* (PGPV), *Psittacinepox virus* (PGPV), *Quailpox virus* (QUPV), *Sparrowpox virus* (SRPV), *Starlingpox virus* (SLPV), and *Turkeypox virus* (TKPV). Other viruses which may be members of the genus but have not yet been approved a separate species include *Crowpox virus* (CRPV), *Peacockpox virus* (PLPV) and *Penguinpox virus* (PEPV). APV fall into three major clades of phylogenetically related viruses. The first one (Clade A, 7 subclades) is related to FWPV which is the prototypic member of the genus, and the causal agent of a widespread, enzootic disease of domestic chickens and other gallinaceous birds. The second one (Clade B, 3 subclades) is related to CNPV which causes high mortality rates to songbirds such as canaries and magpies and the third clade (Clade C) comprises the psittacine PV.

Virion Structure

Since the recognition of APV and orthopoxviruses as the causative agents of disease in the early decades of the nineteenth century, scientists have striven to elucidate their structure. Nevertheless, it has only recently become possible to acquire data on the precise location of poxvirus structural proteins at subviral resolution by using super-resolution microscopy and computational tools. Most

structural studies in poxviruses (PV) have been focused on the archaetypal poxvirus vaccinia virus (VACV), which is the vaccine strain that eradicated smallpox (variola virus).

In common with the other PV, APV are large viruses (about $330 \times 280 \times 200$ nm) that can just be seen by light microscopy. Electron microscopy revealed that APV display the characteristic brick or ovoid morphology with a biconcave viral core. The viral core contains the linear dsDNA genome and enzymes for the virus uncoating and genome replication. It is enclosed by a lipoprotein envelope and flanked by two protein structures called the lateral bodies. All these structures are contained within an outer coat composed of randomly arranged surface tubules. The role of lateral bodies is not entirely clear and until recently it was proposed to be merely structural. Recent studies in VACV (and FWPV; unpublished) suggest that lateral bodies pack immune modulatory proteins, which can be delivered (upon virus uncoating) into the cytoplasm of target cells. They can therefore serve as facilitators of an early innate immune evasion strategy.

Genome

APV have a single, unsegmented, linear molecule of double-stranded DNA (260–365 kbp) and encode on average more than 230 proteins. Their genome has a low GC-content (30%–40%) compared to >60% for parapoxviruses and molluscipoxviruses and 20% for entomopoxviruses. Similar to all PV, the central region of their genome is flanked by two identical inverted terminal repeats covalently linked by hairpin loops. The central region contains nearly 100 relatively conserved (among *Chordopoxviruses*) genes, which encode viral DNA replication, transcription and RNA modification, and virion formation. The terminally located genes are more prone to mutation and recombination, are thus more variable and encode proteins typically involved in host range restriction, immunomodulation and pathogenesis.

Although APV have evolved to infect a wide range of avian species, to date only few complete APV genomes are available (Table 1); a pathogenic strain of *Fowlpox virus* (FPVUS), an attenuated strain of *Fowlpox virus* (FP9), a virulent *Canarypox virus* (VR-111), a pathogenic South African strain of *Pigeonpox virus* (FeP2), a *Penguinpox virus* (PSan92), a pathogenic strain of *Turkeypox virus* (HU1124), a *Flamingopox virus* (FGPVKD09) and two novel avipoxviruses from Pacific shearwaters (*Ardenna* spp; SWPV-1 and SWPV-2).

A comparison of the available APV genomes revealed overall synteny in their genome arrangement. There are however significant differences (i.e., gene duplications, translocations etc) both in the terminal and the internal regions in contrast to the high levels of conservation of central genomic regions in orthopoxviruses. Comparison of the plaque-purified tissue culture-adapted attenuated European strain FP9 with the US virulent FWPV strain revealed 118 differences, of which 71 genes were affected by deletion (26 of 1–9334 bp), insertion (15 of 1–108 bp), substitution, termination or frame-shifts. Only 110 (42%) of FWPV genes share significant similarity to those in other PV. The CNPV genome is about 80–100 Kbp larger than FWPV, with 39 genes lacking FWPV homologs and approximately 47% amino-acid divergence primarily in the terminal variable regions. The TKPV genome is considerably smaller than the other APV genomes. FeP2 and PEPV are more closely related to FWPV but the presence of whole or disrupted genes that are absent in FWPV but similar to CNPV sequences, suggests that they originate from a common ancestor of CNPV and FWPV. The DNA sequences of SWPV-1 and SWPV-2 are significantly different from each other but nevertheless have good similarity with CNPV (67% and 98% respectively). Genomic profiles of mynahpox, and quailpox viruses show marked differences from FWPV. Compared to mammalian PV, APV show considerable genome reorganization. The most closely related mammalian PV are the molluscipoxviruses and parapoxviruses with which APV share key aspects of gene organization as well as several aspects of immunomodulation and pathogenesis.

Many field FWPV strains carry an active copy of the retrovirus reticuloendotheliosis virus (REV). REVs are closely related to mammalian retroviruses and have also been reported in the gallid herpesvirus 2 (GHV-2) that causes Marek's disease in chickens

Fig. 1 The replication cycle of APV. Certain elements of the schematic are from Motifolio.

and other galliform birds. The origin of REV insertion into the APV genome is a point of conjecture. Current theories propose that REV endogenization is either due to an ancestral insertion event following natural infection or that it has instead a iatrogenic origin. The REV insertion may account for the strains' increased virulence and fitness. Certainly, REV has been considered one of the most important vaccine contaminants as it can interfere with vaccine-induced immunity. Several vaccine strains (i.e., FPV-S) have already been withdrawn from the market over fears that they are contaminated with REV. Nevertheless, most passaged laboratory and commercial vaccine strains appear to have lost most of the provirus, sometimes leaving only a single long terminal repeat sequence. In these cases the inserted REV sequences cannot give origin to a replication competent virus and therefore should not pose risks for the vaccinated animals.

Life Cycle

The life cycle of PV, illustrated in [Fig. 1](#), is a highly conserved (among *Chordopoxviruses*) and complex sequence of events that commences with the binding of PV onto the cell surface and ends with the release of virions from the cells. APV replicate exclusively in the host cell cytoplasm and have two distinct infectious virus particle types: the unenveloped mature virus (MV) or intracellular MV (IMV) and the extracellular enveloped virus (EEV). The MV and EEV virions differ in their surface glycoproteins and number of surrounding membranes and can both initiate infection.

Viral entry involves either macropinocytosis followed by fusion of the viral envelope and the endocytic vesicle membrane or direct fusion of the virion with the plasma membrane. Upon fusion, the viral cores containing the viral DNA, viral transcription factors, and RNA polymerases pre-bound to early promoters, are liberated into the host cell cytoplasm and undergo a morphological modification termed activation. Core activation includes the switching of the virion shape from biconcave to oval, the uncoupling of the lateral bodies and the initiation of early viral gene expression under the control of viral early promoters. This step is followed by the rupture of the core structure, which releases the viral DNA into the cytoplasm. DNA replication is initiated immediately and is followed by two waves of transcription (intermediate and late), which are mediated by host-derived transcription factors. The newly synthesized viral DNA serves as a template for the subsequent cycles of genome replication and for the transcription of viral genes. Replication and virion assembly take place in cytoplasmic structures called virus factories or viroosomes.

APV generally undergo the various morphogenic stages similar to VACV but with some notable differences. Electron microscopy studies in FWPV showed that the first viral structures are crescent-shaped structures, formed in the virus factories, that begin to incorporate viral DNA. These structures develop into spherical immature virions (IV), which subsequently mature into the characteristic infectious brick- or ovoid-shaped IMVs. The two-lipid bilayer membranes of IMVs derive from the compartment between the endoplasmic reticulum and the *cis*-Golgi cisternae. In VACV, IMVs can either remain in the cells until cell lysis, bud through the plasma membrane or acquire an additional bilayer membrane by a process called "wrapping". The VACV intracellular enveloped virions (IEV), formed after wrapping, migrate by actin tails to the cell surface where the external membrane of the virus

fuses with the plasma membrane, releasing EEV. In contrast to VACV, electron microscopy and proteomic studies have demonstrated that FWPV, CNPV and PGPV lack some of the key genes involved in the wrapping step and the formation of actin tails. FWPV and CNPV appear to exit cells predominantly by budding of the IMV through the plasma membrane to form EEV.

Epidemiology

The epidemiology of the APV is still unclear, due to a lack of studies, the scarcity of genomic data and consequent inability to accurately assign viral isolates into species. APV appear fairly host restricted, but the picture is complicated because many atypical species-species transmissions can occur e.g., prey to predator transmissions, close proximity of diverse animals in zoos and animal facilities etc. APV are considered a threat to both passerine and non-passerine birds including endangered species. Dramatic losses of passerine birds caused by CNPV-like viruses have been reported worldwide in wildlife ecosystems such as in Hawaii, the Galapagos, Australia and New Zealand. Hosts included Andean condors, Australian magpie, Currawongs, Hawaiian crows and geese, palila, apapane and silvereyes. Since the 1950s, APV have been reported in a number of bird species including blackbirds, carrion crows, chaffinches, doves, dunnocks, goldfinches, greenfinches, starlings, jackdaws, pigeons, and sparrows. Since 2005, there has been a marked increase in reports of APV in great tits, with the disease confirmed in several central and northern European countries including the UK. Blue and coal tit populations have been less affected. APV outbreaks have been associated with wildlife translocations or human interventions. However, without long-term data on the (sero)prevalence of APV in wild birds, it is difficult to trace the infection sources and assess the associated risks for wild life.

APV are transmitted via biting insects (e.g., mosquitos, mites, flies) and/or aerosols and invade birds through broken skin. The transmission potential of APV has been suggested to be correlated to the range of insect vector populations. In the face of climate change, seasonal and geographical shifts of insect populations may have broad repercussions in future outbreaks of APV. FWPV (and most likely all APV) is resistant and can survive in the environment for extended periods of time in desiccated scabs shed from infected hosts. Resistance is due to embedment of viruses within large cytoplasmic inclusions and production of photolyase which protect virions following cell lysis and during their environmental exposure.

Pathogenesis

Studies in domestic poultry with FWPV and in canaries with CNPV have been responsible for most of the information currently available in APV pathogenesis. There is evidence that the effects of APV can vary in different avian species. The generalized pathogenicity model is that APVs replicate at the site of inoculation and cause dermal hyperplasia (pock lesions) and leukocyte infiltration. APV infection is typically found in one of two forms: the cutaneous and the diphtheritic form. Both forms can occur at the same time. A third rare systemic form (generalized) can also occur occasionally in canaries, causing primarily depression and anorexia. The cutaneous form of the disease ('dry' pox) is relatively mild and usually characterized by nodular, proliferative growths that are most commonly restricted to the eyes, beak or unfeathered skin of the body. Atypical forms of dry pox can be found in the feathered skin of the birds i.e., feather folliculitis. Infection is slow-developing and can become persistent and extensive although most often is self-limited. With few exceptions, dry pox only causes a drop in productive performance of birds. The nodular lesions are rarely fatal but may restrict the birds' vision and ability to hunt/forage thus making them more susceptible to predation and secondary infections. In canaries the cutaneous lesions can be accompanied by often severe inflammation mainly in the periocular space that may be complicated by secondary infections.

Inhalation or ingestion of aerosols from the dried scabs can lead to more severe infection the so-called "diphtheritic infections" ("wet pox"). This is characterized by fibronecrotic lesions on the mucous membranes of the respiratory and digestive tracts. These lesions resemble those of the avian herpesvirus infectious laryngotracheitis virus. Symptoms of wet pox also resemble those of other avian viruses that cause upper respiratory disease such as avian influenza, or Newcastle Disease virus, thus complicating initial diagnosis. Wet pox causes up to 15% mortality in chicken flocks by occlusion of the larynx and/or secondary bacterial/fungal infections. Upon histological examination of FWPV-infected tissues, variably sized and often large, eosinophilic intracytoplasmic inclusions (Bollinger bodies) can be observed with elementary bodies called Borrel's bodies. Other confirmatory techniques for laboratory diagnosis of FWPV include PCR, electron microscopy and viral culture.

The mortality associated with FWPV disease in poultry is usually low, but in flocks under stress, mortality can reach up to 50%. CNPV is generally associated with higher mortality rates (approaching 100%) often without the characteristic skin lesions.

Host range

FWPV affects mainly chickens and turkeys and has been reported to infect ducks, geese, pheasants, quail, canaries and hawks. Mammals are not susceptible to natural infection with FWPV (or any of the other APV). Nelson (1941) reported mild pathology in mice following intranasal inoculation with FWPV, with no virus replication. Atypical infections have also been reported (i.e., rhinoceros). More recent (albeit limited) studies have shown the presence of infectious viral particles and CPE of FWPV in mammalian cell cultures, such as embryonic bovine tracheal cells and baby hamster kidney cells. These studies challenge the general dogma that FWPV cannot undergo a full replication cycle in mammalian cells. Unlike the FWPV-like, the CNPV-like APV appear able to infect a wider range of avian species. CNPV causes mild infection to its most likely natural hosts, the native songbirds of temperate climes, and more severe infections in non-native canaries.

The target cell determinants of PV binding are thought to be ubiquitously expressed glycosaminoglycans and no specific cell receptors are yet known to be required for virion fusion and cell entry. Host range restriction of PV is attributed to post-entry events associated with antiviral mechanisms such as the type I IFN response or T-cell responses.

Immunomodulation

PV have developed strategies to prevent or evade early host innate responses induced as a consequence of the viruses' binding/fusing with the cell membrane and their progressive migration through diverse cell types and tissues. APV encode many gene homologs with possible host range functions such as chemokine-like molecules (e.g., fpv061, fpv121), putative chemokine receptors (e.g., fpv021, fpv206) as well as inhibitors and homologs of genes involved in apoptosis, autophagy, cell growth and various signaling cascades. Both FWPV and CNPV encode mimics of transforming growth factor (TGF)- β , and CNPV encodes an IL-10-like protein. These proteins are predicted to stimulate regulatory T-cells and suppress the host inflammatory responses. Viral mimicry of cytokines, chemokines and their receptors is well documented in orthopoxviruses. Whether APV use similar mechanisms to evade detection and destruction by the host immune system remains to be confirmed upon availability of chicken reagents.

Our understanding of the strategies deployed by APV to disarm the interferon (IFN) response, the first line of host defense against invading viruses, remains rudimentary and is limited to few FWPV immunomodulatory proteins. FWPV and CNPV (unpublished), unlike other avian viruses (e.g., infectious bursal disease virus) do not induce type I IFN response in chicken embryo fibroblast culture. Moreover, both the wild-type pathogenic FWPV and the attenuated vaccine strain FP9 can block the induction of expression of the chicken interferon β (ChIFN2) promoter normally seen upon transfection with the dsRNA analog, poly(I:C). A broad-scale loss-of-function genetic screen involving a library of 48 FWPV in vitro-generated mutants, each defective in a single, nonessential gene, identified *fpv012* as a modulator of poly(I:C)-mediated ChIFN2 induction. *fpv012* is a member of a family of genes that are highly expanded in the APV (31 in FWPV; 51 in CNPV), encoding proteins containing N-terminal ankyrin repeats (ANKs) and C-terminal F-box-like motifs (ANK-PRANC proteins). Under ectopic expression, the first ANK of *fpv012* is dispensable for inhibitory activity and the CNPV ortholog is also able to inhibit induction of ChIFN2. Conversely, a gain-of-function approach in which 4–8 kbp fragments of the FWPV FP9 strain were introduced into the vaccine strain modified vaccinia Ankara, identified that another ANK-PRANC protein (FPV014) contributes to increased resistance to exogenous recombinant chicken IFN- α .

Control & treatment

FWPV infections in chickens and turkeys are generally well controlled with a standard vaccination program. The timing of vaccinations is dictated by the number of affected birds in a flock (when <20% of the birds have lesions), the onset of disease, the flock size and the type of commercial operation. Modified live FWPV, and PGPV vaccine strains of cell-culture origin are commercially available. The vaccines are usually applied by the wing-web stick method (or thigh-stick methods for turkeys), or injection between the age of 10–14 weeks of age. Birds can be vaccinated at any age if necessary. In some areas where mosquito populations are present throughout the year two vaccinations per year are used. For CNPV infections in pet canary birds and other passerine birds, a live attenuated CNPV vaccine is considered the best preventive measure. Vaccination could also play a role in the conservation management of other endangered avian species that are significantly affected by APV disease. Transmission prevention measures include an insect control program, the improvement of farm hygiene and animal husbandry practices (e.g., dust control, disinfection, ventilation, prevention of fighting of male birds in bird housing, quarantine procedures).

Currently there is no treatment available and diseased birds are treated symptomatically i.e., by washing and sterilizing infected areas, removal of necrotic tissues from mouth and throat of infected birds etc. In the event of an outbreak, disinfecting water lines with a liquid iodine disinfectant, appears to reduce mortality. Broad-spectrum antibiotics and vitamin supplements are beneficial for the birds if there is evidence of secondary bacterial infection.

Use of APV as recombinant vaccine vectors

There is no known zoonotic risk associated with APV. APV cause a productive infection in avian hosts and a non-productive or abortive infection in mammalian hosts. This feature allowed the development of host-restricted APV vectors as safe platforms for vaccines or gene delivery including CNPV (ALVAC) and FWPV (TROVAC). Other desirable features that make APV ideal vaccine vectors include their large genome size which supports a large coding capacity, their ability to readily enter most vertebrate cells to express antigens and their ability to modulate the host innate and adaptive immune responses. Numerous attenuated, live APV-based vaccine strains have been developed since the 1920s against diverse pathogens including avian influenza, Newcastle disease, rabies, cancer, some of which are currently tested or in use in both veterinary and human medicine. A landmark vaccination campaign using for the first time recombinant FWPV was employed successfully in Mexico in the mid-1990s to control high pathogenicity avian influenza H5N2 with almost a billion doses used. Since then, recombinant FWPV have been used in large-scale vaccinations in China, Southeast Asia and elsewhere.

The subject of APV vaccine-vector development is beyond the scope of this article and has been comprehensively reviewed by others. As more information is gathered on APV virulence, immune evasion and host range, it is likely that this knowledge will facilitate the engineering of safer and more efficient vectors for vaccines and gene therapy.

Glossary

Coevolution Evolution of a virus together with its reservoir host.

Hantavirus A virus in the genus *Orthohantavirus*.

Reassortant A virus having genome segments of two different viruses.

Historical Introduction

Hantavirus infections are not new to humankind. The first description of a hemorrhagic fever with renal syndrome (HFRS)-like disease can be found in a Chinese medical account written in about AD 960 and the earliest definite description of HFRS comes from Far East Russian clinical records dating back to 1913. During World Wars I and II, HFRS became an important military problem; for example, 'field nephritis' in Flanders during World War I may well have been caused by a hantavirus. In Manchuria in the mid-1930s, 12,000 Japanese soldiers caught the disease and military researchers were investigating the cause of the disease, sometimes using prisoners of war in infection experiments. Finnish and German soldiers encountered an HFRS-like epidemic in Finnish Lapland in 1943–1944. During the Korean conflict in 1950–1953, the disease gained again much attention when about 3000 United Nations troops contracted it – since then known as Korean hemorrhagic fever – with a 5%–10% case–fatality rate. The milder form of HFRS, nephropathia epidemica (NE), common in Fennoscandia (Scandinavia and Finland), was first described by Swedish authors in 1934. However, the infecting agent of HFRS remained unknown until 1976, when the Korean researcher Ho Wang Lee discovered that cryostat-sectioned lungs of striped field mice (*Apodemus agrarius*), trapped near the Hantaan river, contained virus-specific antigen reactive with HFRS-patient sera. By a similar approach, the causative agent of NE was demonstrated in 1980 in bank voles, *Myodes glareolus*, trapped in Puumala, Eastern Finland. Another agent, which identified in urban rats in Seoul, Korea, was also found to cause HFRS. In the early 1990s, a further distinct European human-pathogenic hantavirus was isolated from the yellow-necked mouse, *Apodemus flavicollis*, near the village of Dobrava in Slovenia, and a few years later, a related, less pathogenic variant, Saaremaa virus from striped field mice on Saaremaa Island, Estonia. Thottapalayam virus from an insectivore (*Suncus murinus*, a shrew) in India, Prospect Hill virus from a meadow vole (*Microtus pennsylvanicus*) in USA, and Thailand virus from a bandicoot rat (*Bandicota indica*) had already been isolated in the early 1970s to the 1980s – apparently they all are nonpathogenic for humans.

Human disease had not been known to be caused by a hantavirus in the Americas until a cluster of acute respiratory distress syndrome cases with a high (40%) case–fatality rate in the Four Corners area of Southwestern USA (where Arizona, Utah, Colorado, and New Mexico are contiguous) was recognized in May 1993. Subsequent studies led to the discovery of Sin Nombre virus and other hantaviruses that cause hantavirus cardiopulmonary syndrome (HCPS), all transmitted from sigmodontine rodents indigenous to the New World. An increasing number of pathogenic hantaviruses have been reported in South America, including Andes virus, which can be transmitted from person to person, and which possess high case–fatality rates. While only a few thousand HCPS cases have been reported so far, approximately 50,000 HFRS cases are estimated to occur worldwide annually.

In the era of advanced sequencing methods, the rate of hantavirus discovery has accelerated. A great majority of the novel hantaviruses are carried by soricomorpha hosts, i.e., shrews and moles, and few of them by insectivorous bats. These variants appear to be non-pathogenic to humans. In 2016, the new order Bunyavirales was established, elevating the previous genus Hantavirus to the family *Hantaviridae*. Simultaneously, the species demarcation criteria were updated and the family was divided into 4 subfamilies, 7 genera, and 47 species. The hantaviruses causing human infections belong to the subfamily *Mammantavirinae* and genus *Orthohantavirus*.

Virology

Hantaviruses are enveloped viruses with a tripartite negative-stranded RNA genome (Fig. 1). The 6.4 kb L (large) genome segment encodes a ~250 kDa RNA polymerase, the ~3.6 kb M (medium) segment, two glycoproteins 68–76 kDa Gn and 52–58 kDa Gc (formerly known as G1 and G2), and the ~1.7 kb S (small) segment a 50–54 kDa nucleocapsid protein (N). In addition, the S segment of hantaviruses carried by cricetidae rodents has another overlapping (+1) open reading frame (ORF) named NSs, which has been shown to inhibit the interferon response. Viral messenger RNAs of the members of the *Bunyaviridae* are not polyadenylated and are truncated relative to the genomic RNAs at the 3' termini. Messenger RNAs have 5'-methylated caps and 10–18 nontemplated nucleotides derived from host cell mRNAs. The termini of all three segments are highly conserved and complementary to each other, a feature that has assisted in cloning and discovery of new hantaviruses (Fig. 2).

Fig. 1 Structure of an orthohantavirus. (a) The hantavirus particle contains the trisegmented viral RNA (vRNA) genome, comprising the small, medium and large ORFs. These are encapsidated by nucleocapsid (N) protein. The outer part of the virion consists of spikes comprising four units of each glycoprotein, Gn and Gc. The viral genome is replicated and transcribed by RNA-dependent RNA polymerase (RdRp). (b) A hantavirus particle viewed by cryoelectron microscopy. The spike height is invariably 12 nm, and the median diameter of the virion is 135 nm. Part b image is courtesy of P. Laurinmäki and S. Butcher, University of Helsinki, Finland.

Unlike most other bunyaviruses, hantaviruses are not arthropod borne, their reservoirs are rodents, insectivores or bats. Each hantavirus is primarily carried by a distinct reservoir host species, although several host switches seem to have occurred during tens of millions of years of their co-evolution with their carrier hosts. We now know that the genetic diversity of hantaviruses is generated by (1) genetic drift (accumulation of point mutations and insertions/deletions) leading to mixtures of closely related genetic variants, quasispecies; (2) genetic shift (reassortment of genome fragments within a given virus genotype/species); and (3) to some extent, by homologous recombination.

Ecology and Epidemiology

Hantavirus infections are prime examples of emerging and reemerging infections. Like most of these infections, hantaviral diseases are zoonoses. With the exception of the South American Andes virus, hantavirus infections are thought to be transmitted to humans primarily from aerosols of rodent excreta (feces, urine, saliva). Andes virus has also been shown to be transmitted human-to-human. Infections of hantaviruses in the rodents are asymptomatic and persistent, and have only a minor effect on the host. Some hantaviruses cause disease in humans. In Asia, Hantaan virus, carried by *Apodemus* spp. mice, cause severe HFRS, and Seoul virus, carried by rats, causes a milder disease. In Europe, there are two major hantaviral pathogens: Puumala virus carried by bank voles causes NE, while Dobrava virus (DOBV), carried by yellow-necked or striped-field mice, causes severe HFRS. Four different genotypes of DOBV circulate in Europe: the genotypes Dobrava and Sochi cause severe illness, while the genotypes Kurkino and Saaremaa a mild, NE-like disease. There also are reports that Seoul virus (SEOV), carried by rats (*Rattus norvegicus* and *Rattus rattus*), causes HFRS of moderate severity both in Europe and North America. Recent findings suggest that pet rats may also act as reservoirs of SEOV. In addition, European common voles (*Microtus arvalis* and *Microtus rossiaemeridionalis*) carry Tula hantavirus, which can asymptotically infect humans on rare occasions.

Hantavirus infections are quite common in Europe. Puumala virus occurs in Northern Europe, European Russia, and parts of Central and Western Europe. Dobrava genotype of DOBV is found mainly in the Balkans and the neighboring Central European areas. The genotypes Kurkino and Saaremaa have been detected in Eastern and Central Europe, while the genotype Sochi (carried by *Apodemus ponticus*) is circulating in the southern European Russia. Apart from infections of laboratory rats, Seoul virus has been detected in wild rats in France and in several city harbors. Seoul virus infections from pet rats have been increasing lately in Europe, but also in US. It is apparent that many parts of Europe, and most of Africa, remain completely or relatively unstudied with regard to hantaviruses. This suggests either that HFRS is rare or nonexistent in these regions or is not generally recognized and is not diagnosed by local biomedical communities.

Fig. 2 Life cycle of a hantavirus in an infected cell. The hantavirus virion attaches to a receptor on the cell surface (step 1). This binding event induces endocytosis signaling (step 2), after which the virion enters the cell in clathrin-coated vesicles (step 3). Other entry pathways have also been observed for some hantaviruses. In the case of clathrin-mediated endocytosis, the clathrin coat of the vesicle is disassembled (step 4), and the virion-harboring vesicle enters the early endosome (step 5), which matures into a late endosome (step 6). Fusion between the viral and endosomal membranes is driven by acid-induced conformation changes in the viral fusion protein in the late endosome. This results in release of the viral ribonucleoproteins (RNPs) (step 7). Initial transcription might take place at the site of release; alternatively, the RNPs might be transported to the ER–Golgi intermediate compartment (ERGIC) for transcription. It is also possible that the virus is directly transported to the Golgi complex from the late endosome, either before or after fusion. Viral replication is thought to occur in viral factories that might be located at the ERGIC or the *cis*-Golgi (step 8). The nascent viruses are thought to bud into the *cis*-Golgi (step 9), from where they are transported to the plasma membrane for release, presumably via recycling endosomes. The egress of progeny virions takes place at the plasma membrane (step 10).

In Northern Europe, HFRS as well as the carrier rodents exhibit peaks in 3–4 year cycles, while in Central Europe the HFRS incidence follows the fluctuations of “mast years”, that is, the abundance of beech and oak seeds for the hantavirus-carrying rodents. In Central Europe, HFRS peaks in the summer whereas in Northern Europe most cases occur in late autumn and early winter, from November to January. Risk factors for acquiring hantavirus infections and HFRS include professions such as forestry, farming, and military, or activities such as camping, and the use of summer cottages. Cigarette smokers and males are more likely to be infected than are females. In the Americas, the increased precipitation during El Niño/Southern Oscillation in South and North America has been suggested as the main reason for the peaks in rodent population densities and for the consequent increased number of HCPS cases.

Sigmodontine-borne hantaviruses circulating in North America form three phylogenetically distinct groups: those associated with *Peromyscus* spp. and *Reithrodontomys* spp. rodents, and the third carried by *Sigmodon* spp. and *Oryzomys* spp. rats. The first group carries both human pathogens (Sin Nombre virus) and viruses not thus far associated with human disease (e.g., Blue River virus, Limestone Canyon virus). *Reithrodontomys*-borne viruses have not been shown to cause disease in humans. Hantaviruses discovered in South America are associated with several tribes of Sigmodontinae, mostly Oryzomyini-associated viruses, several of which are important human pathogens, including Andes virus. Results of phylogenetic analyzes of South American hantaviruses suggest that several host-switching events have occurred during coevolution with their rodent hosts. The phylogenetic split

between murine and sigmodontine rodents presumably dates to a divergence that occurred between subfamilies 30 million years ago, when the precursors of the sigmodontine rodents crossed the Bering Strait into the Americas. Notably, sigmodontine rodents are found only in the Americas and thus it is unlikely that HCPS would occur in Eurasia, unless imported.

Clinical Picture and Pathogenesis

Dobrava, Hantaan, Seoul and Puumala viruses all cause HFRS but the infections differ considerably in severity. All are characterized by acute onset, fever, headache, abdominal pains, backache, temporary renal insufficiency (first oliguria, proteinuria, and increase in serum creatinine, and then polyuria), and thrombocytopenia, but the extent of hemorrhages (hematuria, petechiae, internal hemorrhages), requirement for dialysis treatment, hypotension, and case–fatality rates are much higher in HFRS caused by Dobrava, or Hantaan viruses than in NE caused by Puumala or Saaremaa and Kurkino genotype viruses. About a third of NE patients experience temporary visual disturbances (myopia), which is a very characteristic if not pathognomonic sign of the

Table 1 Orthohantavirus types

<i>Virus</i>	<i>Host</i>	<i>Distribution</i>	<i>Disease</i>
MURIDAE-BORNE			
Hantaan (HTNV) ^a	Striped field mouse (<i>Apodemus agrarius</i>)	Asia (Korea)	HFRS
Da Bie Shan	Chinese white-bellied rat (<i>Niviventer confucianus</i>)	Asia (China)	NR
Seoul (SEOV)	Rat (<i>Rattus rattus</i> , <i>R. norvegicus</i>)	Worldwide (Korea)	HFRS
Dobrava-Belgrade (DOBV)	Yellow-necked mouse (<i>A. flavicollis</i>)	Europe (Slovenia)	HFRS
Sangassou (SANGV)	African wood mouse (<i>Hylomyscus simus</i>)	Africa (Guinea)	NR
Thailand (THAIV)	Bandicoot rat (<i>Bandicota indica</i>)	Asia (Thailand)	NR
Tigray (TIGV)	Ethiopian white-footed rat (<i>Stenocephalemys albipes</i>)	Africa (Ethiopia)	NR
CRICETIDAE/ARVICOLINAE-BORNE			
Puumala (PUUV)	Bank vole (<i>Myodes glareolus</i>)	Europe (Finland)	HFRS
Tula (TULV)	European common vole (<i>Microtus arvalis</i>)	Europe (Russia)	NR
Prospect Hill (PHV)	Meadow vole (<i>M. pennsylvanicus</i>)	North America (USA)	NR
Khabarovsk (KHAV)	Reed vole (<i>M. fortis</i>)	Asia (Far East Russia)	NR
Fugong (FUGV)	(<i>Eothenomys eleusis</i>)	Asia (China)	NR
Fusong (FUSV)	Reed vole (<i>Microtus fortis</i>)	Asia (China)	NR
Luxi (LUXV)	Yunnan red-backed vole (<i>Eothenomys miletus</i>)	Asia (China)	NR
CRICETIDAE/SIGMODONTINAE BORNE			
<i>New World mice and rats</i>			
Sin Nombre (SNV)	Deer mouse (<i>Peromyscus maniculatus</i>)	North America (USA)	HCPS
Bayou (BAYV)	Rice rat (<i>Oryzomys palustris</i>)	North America (USA)	HCPS
Black Creek Canal (BCCV)	Hispid cotton rat (<i>Sigmodon hispidus</i>)	North America (USA)	HCPS
Muleshoe (MULV)	Hispid cotton rat (<i>S. hispidus</i>)	North America (USA)	NR
Andes (ANDV)	Long-tailed pygmy rice rat (<i>Oligoryzomys longicaudatus</i>)	South America (Argentina)	HCPS
Choclo (CHOV)	Pygmy rice rat (<i>O. fulvescens</i>)	Central America (Panama)	HCPS
Laguna Negra (LANV)	Vesper mouse (<i>Calomys laucha</i>)	South America (Paraguay)	HCPS
Rio Mamore (RIOMV)	Small-eared pygmy rice rat (<i>O. microtis</i>)	South America (Bolivia)	NR
Caño Delgadito (CADV)	Cane mouse (<i>S. alstoni</i>)	South America (Venezuela)	NR
El Moro Canyon (ELMCV)	Western harvest mouse (<i>Reithrodontomys megalotis</i>)	North America (USA)	NR

Montano (MTNV)	Orizaba deer mouse (<i>Peromyscus beatae</i>)	Central America (Mexico)	NR
Necocli (NECV)	<i>Zygodontomys brevicauda</i>	South America (Colombia)	NR
SORICOMORPHA BORNE			
<i>Insectivores</i>			
Asama (ASAV)	Japanese shrew mole (<i>Urotrichus talpoides</i>)	Asia (Japan)	NR
Asikkala (ASIV)	Eurasian Pygmy Shrew (<i>Sorex minutus</i>)	Europe	NR
Bowe (BOWV)	Doucet's musk shrew (<i>Crocidura douceti</i>)	Africa	NR
Bruges virus (BRGV)	European mole (<i>Talpa europaea</i>)	Europe	NR
Cao bang (CBNV)	Chinese mole shrew (<i>Anourosorex squamipes</i>)	Asia (Vietnam)	NR
Jeju (JJUV)	Asian lesser white-toothed shrews (<i>Crocidura shantungensis</i>)	Asia (Korea)	NR
Kenkeme (KKMV)	Flat-skulled shrew (<i>Sorex roboratus</i>)	Asia (Russia)	NR
Oxbow (OCBV)	American shrew mole (<i>Neurotrichus gibbsii</i>)	North America	NR
Seewis (SWSV)	Common shrew (<i>Sorex araneus</i>)	Europe (Switzerland)	NR
Rockport (RKPV)	Eastern mole (<i>Scalopus aquaticus</i>)	North America (USA)	NR
Yakeshi (YKSV)	<i>Sorex isodon</i>	Asia (China)	NR

^aType species.

Abbreviation: HFRS, hemorrhagic fever with renal syndrome; HCPS, hantavirus pulmonary syndrome; NR, disease not recorded.

disease. Notably, the clinical consequences of all of the hantaviral pathogens in humans vary from none to fatal. Severe NE is associated with a certain haplotype, HLA-B8, DR3, DQ2 alleles, severe HCPS with HLA-B35, and mild NE with HLA-B27. Yet, although Puumala virus infection is generally associated with mild HFRS, NE may have significant long-term consequences. A 5-year follow-up study demonstrated that 20% of NE patients had a somewhat increased systolic blood pressure and proteinuria. This is important, since the infection is relatively common in many areas of Europe. In addition, in some patients, Puumala virus infection may infect the pituitary gland and lead to mortality or at least to hypophyseal insufficiency requiring hormone-replacement therapy. Hormonal deficiencies are common in acute NE and 5 years after the infection, 17% of the patients are diagnosed with a chronic, overt pituitary hormone deficiency.

The pathogenesises of HFRS and HPS are not fully understood. However, it is known that β 3 integrins can mediate the entry of pathogenic hantaviruses and that hantaviruses can regulate apoptosis. We and others have studied the pathophysiology of Puumala virus (PUUV) and other hantavirus infections and have come to the conclusion that vascular leakage induced by bradykinin (BK) is a key element in the pathophysiology. Orthohantaviruses predominantly infect microvascular endothelial cells of different organs in humans, and the vascular permeability can be a direct effect of viral infection in these cells or result of an imbalanced immune response. Other important elements of pathophysiology include thrombocytopenia, complement activation, circulating histones, cytotoxic and regulatory T cells (CTLs and T regs), certain cytokines (IL-6 and TNF- α in particular) and neutralizing antibodies. In the novel therapy we have successfully blocked vascular leakage in several very severely ill hantavirus-infected patients by the BK receptor antagonist icatibant. Recent developments of both primate and Syrian hamster models that mimic hantavirus diseases should assist in elucidating the mechanisms of pathogenesis.

Hantavirus disease in the Americas is characterized by pulmonary edema but death often results from a cardiac failure; thus the term hantavirus cardiopulmonary syndrome (HCPS) has been proposed for the disease. HFRS and HCPS, although primarily targeted at kidneys and lungs, respectively, share a number of clinical features, such as capillary leakage, increased serum TNF- α levels, and thrombocytopenia; notably, hemorrhages and alterations in renal function occur also in HPS and pulmonary involvement is not rare in HFRS.

Of the four structural proteins, both in humoral and cellular immunity, the nucleocapsid protein appears to be the principal immunogen. Cytotoxic T-lymphocyte responses are seen in both HFRS and HPS and may be important for both protective immunity and pathogenesis in hantavirus infections.

Diagnostics and Prevention

The diagnosis of an acute hantavirus infection is primarily based on serology. Both immunofluorescence tests and enzyme immunoassays are widely used for the detection of specific IgM or low-avidity IgG antibodies, characteristic for an acute infection. In addition, immunochromatographic 5 min IgM-antibody tests have been developed. Hantaviruses show extensive serological cross-reactivity, especially within each of the three virus subgroups (murid, arvicolid, and sigmodontine borne; [Table 1](#)), but for accurate typing, neutralization tests are needed. For example, in Paraguay, a considerable seroprevalence of hantavirus antibodies, as high as 40%, is noted in people without a history of HCPS. Average seroprevalence in Finland and Sweden suggest that only 10%–25% of Puumala virus infections are diagnosed; thus, most infections are either subclinical or mild or atypical and remain undiagnosed.

Viral RNA can usually be detected in the blood of HCPS and HFRS patients using polymerase chain reaction with samples collected during the first week of illness, which is useful because it also identifies the infecting virus genotype.

Vaccines against hantaviral infections have been used for years in China and Korea, but not in Europe or the Americas. A candidate pan-hantavirus vaccine has been reported to be protective in animal models, but is not yet in clinical trials. No specific antiviral therapy is used in Europe, but both ribavirin and interferon- α have been administered in trials in China. A single dose of icatibant, a bradykinin receptor antagonist, has been successfully used to treat patients with severe HFRS caused by Puumala. A major problem is that at the time the patients are hospitalized, the rate of virus replication is already declining, thus the reduction of virus replication by antiviral drugs is no longer necessary for the patient. Thus, prevention of hantaviral infections continues to rely on reduced contact with excreta from infected rodents.

Glossary

Biosafety level 4 A biosafety level is a set of biocontainment precautions required to isolate dangerous biological agents in an enclosed laboratory facility. The levels of containment range from the lowest biosafety level 1 (BSL-1) to the highest at level 4 (BSL-4).

Pteropid bats These are among the largest bats in the world taxonomically placed within the genus *Pteropus*. They are commonly known as fruit bats or flying foxes and live in the tropics and subtropics of Asia (including the Indian

subcontinent), Australia, East Africa, and some oceanic islands in the Indian and Pacific Oceans. There are at least 60 extant species in the genus.

Rule-of-six It describes a requirement for paramyxoviruses to have a genome length with a multiple of six nucleotides for efficient virus replication.

Zoonosis A zoonosis is an infectious disease that is transmitted between species from animals other than humans to humans or from humans to other animals.

Introduction

Hendra virus (HeV), the first henipavirus, was isolated in 1994 following an outbreak of acute respiratory disease in horses in a stable in Brisbane, Australia. In a period of less than three weeks, 21 of 30 horses became infected and 14 either died or were euthanized. Two people who worked at the stable also became infected and one died. Since the initial outbreak in 1994, there have been at least 60 recognized occurrences of HeV in Australia, with at least one occurrence per year since 2006.

The second member of the genus, Nipah virus (NiV), emerged in 1998–99 in Perak State, Peninsular Malaysia as the cause of an outbreak of respiratory and encephalitic disease of low morbidity and mortality in pigs. The virus spread to humans causing febrile encephalitis among pig farmers and those who had a direct contact with pigs in Malaysia and Singapore, resulting in more than 100 human casualties.

A highly related variant of NiV emerged in Bangladesh in 2001, and outbreaks of human NiV infections have been detected from that country almost every year since 2001. At least three separate NiV outbreaks have occurred in India, from east Bangladesh-adjacent regions to the Kerala state on the west. In 2015, an outbreak of NiV or closely related virus occurred in the Philippines with lethal infections in both horses and humans.

In addition to the six countries where henipavirus outbreaks have been detected in humans, molecular and serological evidence suggests that henipavirus or henipa-related viruses are present in bats from Australia and Indonesia in the east to Madagascar and west Africa. Three other henipaviruses have been discovered since 2009: Cedar virus was isolated from flying fox in Australia, the full-length genome sequence was determined for the Ghana virus from bats in Ghana and Mojiang virus from rats in China.

Classification

When the full-length genome sequence of HeV was determined, it was clear that it represented a previously unknown member of the family *Paramyxoviridae*, subfamily *Paramyxovirinae*, but one with unique genetic features that precluded classification in the existing three genera *Morbillivirus*, *Respirovirus* or *Rubulavirus* in the subfamily at that time. Complete genome sequencing of NiV revealed a high degree of similarity to HeV and in 2002, the genus *Henipavirus* was created to accommodate these novel paramyxoviruses.

In the latest report from the paramyxovirus study group released in 2019, the genus *Henipavirus* has been expanded to include three new species, Cedar henipavirus (Cedar virus, CedV), Ghanaian bat henipavirus (Ghana virus, GhV) and Mojiang henipavirus (Mòjiāng, MojV). *Henipavirus* is now classified as one of the seven ICTV-approved genera in the family *Paramyxoviridae* (Fig. 1).

Virion Structure

Henipavirus particles are pleomorphic, varying from spherical to filamentous and ranging in size from 40 to 1900 nm. Nucleocapsids, composed of three major structural proteins (nucleocapsid protein, phosphoprotein and a large protein or RNA-dependent RNA polymerase), have a diameter of 18–19 nm with an average pitch of 5 nm. Examination by electron

Fig. 1 Phylogenetic tree derived from the RdRP proteins of selected henipaviruses and prototype species of the other genera in the family *Paramyxoviridae*. The tree was constructed by using Neighbor-Joining approach with 1000 bootstrap replicates. Numbers at the nodes represent bootstrap values. Scale bar indicates amino acid substitutions per site. Genbank accession numbers are provided in brackets on the right.

microscopy revealed that HeV has a unique double-fringed appearance, caused by the presence of surface projections 15 ± 1 nm and 8 ± 1 nm in length. In contrast, NiV possesses a single layer of surface projections with an average length of 17 ± 1 nm.

Genome

Several molecular features distinguish henipaviruses from other paramyxoviruses. When the genome length of HeV was revealed at 18,234 nucleotides (nt), it was approximately 15% larger than all known paramyxoviruses at that time. The genomes of the Malaysian (MY, 18,246 nt) and Bangladesh (BD, 18,252 nt) strains of NiV differ by 6 nt because of a 6-nt insertion in the 3' untranslated region of the F gene in NiV-BD. The large genome size of > 18 kb is a conserved feature of all henipaviruses known to date, including the more divergent CedV, GhV, and MojV with genome sizes varying between 18,162 nt (CedV) to ~18,430 nt (GhV).

It is not the additional length per se that is unique to henipaviruses. For example, we know now that the genomes of J virus and Beilong virus in the family *Paramyxoviridae* are over 19,000 nt in length. The novel henipavirus genomic feature is the length of the untranslated region at the 3' end of five of the six genes, which in most cases are from 3 to 13 times longer than their *Paramyxoviridae* counterparts. The function of these regions is unknown. Another unique feature of henipaviruses is the increased size of the P protein, at 707 and 709 aa for HeV and NiV, respectively. This is more than 100 aa larger than most of the known paramyxovirus P proteins.

For all members of the family *Paramyxoviridae*, the genome length can be divided by six, due to the requirement of each N protein in the viral ribonucleoprotein to bind 6 nt residues. This "rule-of-six" is also true for henipaviruses despite their much larger genome sizes. The importance of this has been functionally demonstrated for henipaviruses using minigenome replicon assays.

The genome organization of henipaviruses resembles that of the genera *Respirovirus* and *Morbillivirus*. As for other paramyxoviruses, the first 12 nt of the 3' and 5' genomic terminal sequences of henipaviruses are highly conserved. The first 3 nt of the genome termini are 5'-ACC-3' – a sequence that is fully conserved in the family *Paramyxoviridae* and different from that found in the family *Pneumoviridae*.

There are six coding genes in the henipavirus genome coding for the following major proteins (from 3' to 5' order of the genome): nucleocapsid protein (N), phosphoprotein (P), matrix protein (M), fusion protein (F), receptor binding protein (RBP, previously known as G) and RNA-dependent RNA polymerase (RdRp, also known as L). A comparison of henipavirus genome structure to other well known paramyxoviruses is provided in Fig. 2.

Similar to other paramyxoviruses, the henipavirus P gene undergoes transcriptional editing to produce 5'-co-linear mRNAs which result in the production of V, W and C proteins in addition to the P protein. These additional accessory proteins play a role in antagonizing host innate immune responses. However, the CedV P gene lacks the coding capacity for these additional proteins.

Life Cycle

Henipaviruses can replicate in a variety of mammalian cell lines. The rate of replication, the size of syncytia generated, and the location of nuclei in syncytia vary depending on the cell type and virus species. Infected Vero cell monolayers yield titers in excess

Fig. 2 Genome size and organization of Hendra virus in comparison with the type species of the three other most characterized genera in the family *Paramyxoviridae*. Abbreviations: N = nucleocapsid protein; P = phosphoprotein; M = matrix protein; F = fusion protein; RBP = receptor binding protein (formerly G protein); RdRp = RNA-dependent RNA polymerase.

of 10^8 infectious virions per milliliter. The broad host range of henipaviruses has been demonstrated by the multiple natural susceptible hosts from bats, horses, pigs, humans to cats, dogs and rats. This is further corroborated by experiments with direct infection of cells of different species using live virus or pseudotyped viruses containing the F and G/RBP proteins of henipaviruses, and vaccinia virus-mediated cell surface expression of F and G/RBP glycoproteins. The wide host range of henipaviruses is considered uncommon for paramyxoviruses, which usually adopt a narrow host range.

The ephrin B ligands, functioning in the cell-cell signaling with their cognate EphB receptors, have been identified as the entry receptor for henipaviruses with ephrin-B2 being the main receptor and ephrin-B3 and other homologs as alternative receptor(s). The ephrin proteins are highly conserved among vertebrates, which explains, at least in part, the unusually broad species tropism of henipaviruses. Ephrin-B2 is expressed in arteries, arterioles, and capillaries in multiple organs, including neurons, arterial smooth muscle and bronchiolar epithelial cells. In the brain, ephrin-B3 is expressed at a higher level than ephrin-B2. It should be noted that mice are less susceptible to henipaviruses although the level of ephrin B expression is similar, indicating that other factors, in addition to the receptor molecules, play a role in the overall susceptibility of a mammalian host to henipaviruses.

For susceptible hosts, data obtained from field and laboratory studies indicate an oronasal or oropharyngeal route of entry. The initial site of replication is mostly localized within the respiratory system. Secondary infection can occur in most organs, but with key lesions associated with the respiratory and CNS system, most likely via hematogenous spread of the virus with replication occurring in vascular endothelium. Inflammation of blood vessels (vasculitis) occurs in most organs but is particularly prominent in the brain, lungs, heart, kidneys and spleen.

It is important to note that while human lymphocytes (mainly T and B cells), and monocytes are not permissive for henipavirus infection, it has been shown that they can nevertheless bind and transfer NiV to permissive microvascular endothelial cells. This trans-infection phenotype may play an important role in the hematogenous spread of the virus in addition to the free form that makes up the plasma viremia seen in human patients in the acute phase of the lungs.

Epidemiology

Human henipavirus infections in Australia and the Philippines and in Malaysia occurred as a result of transmission of the viruses from flying foxes via horses and pigs, respectively. In contrast, NiV may have been directly transmitted to humans in Bangladesh (and India, with less direct evidence) where it is believed that date palm juice contaminated with bat secretions constituted a potential transmission route. The mode of transmission from bats to spillover hosts is not known. It has been suggested that horses and pigs may have been infected by HeV and NiV through masticated fruit pulp discarded by flying foxes or by flying fox urine which contaminated pastures or pig sties. Alternatively, the source of virus may have been infected fetal tissues or fluids, a suggestion based on the fact that HeV outbreaks occurred during the birthing period of some species of flying fox, the isolation of HeV from a pregnant flying fox and its fetus, and the transplacental transmission of HeV in experimental infections.

HeV has been transmitted from horses to humans in four occasions. The source of the virus may have been the saliva of infected horses, the nasal discharge commonly found at the terminal stages of the disease, or a wide range of infected tissues made

Table 1 List of countries where infection of Nipah or Nipah-related virus in bats has been detected

accessible by necropsy. The paucity of virus in the bronchi or bronchioles of infected horses suggests transmission of HeV to either man or horse by aerosol is highly unlikely and experimental infection has confirmed the poor transmissibility of HeV in horses.

Risk factors for human infection by NiV in Malaysia were contact with pigs or fresh pig products and because the virus was present in a wide range of organs, the greatest likelihood arose for those in direct contact with sick or dying pigs on farms during farrowing or slaughtering or in abattoirs. NiV is readily observed in the respiratory epithelium of naturally and experimentally infected pigs, a feature suggesting that the virus probably spread to humans and within the pig population by aerosol or by direct contact with oropharyngeal or nasal secretions. Although NiV was present in the urine and respiratory secretions of patients, human-to-human transmission in Malaysia was extremely rare. In contrast, in Bangladesh, epidemiologic evidence indicates the spread of the virus from one person to another.

Fruit bats (flying foxes) in the genus *Pteropus*, family *Pteropodidae*, suborder Yinpterochiroptera (previously known as Megachiroptera) are the main reservoir hosts of HeV and NiV. In Australia, HeV has been shown to occur in all four flying fox species. In other parts of the world, serologic tests have shown that NiV or NiV-related virus is widely distributed in bats from Indonesia to the west border of Africa. In Australia, HeV has been isolated from at least bats of two different species, *Pteropus alecto* and *Pteropus poliocephalus*. NiV was first isolated from the urine of Island flying foxes and from the saliva on partially eaten fruit and has since been isolated from Lyle's flying foxes (*Pteropus lylei*) in Cambodia and *Pteropus medius* in Bangladesh. In addition to direct isolation, the presence of NiV in different bat populations has also been demonstrated by either molecular or serological detection in the following countries or regions: Annobón, Bangladesh, Bioko, Cambodia, Cameroon, China, Ghana, India, Madagascar, Malaysia, Malawi, Príncipe, Rio Muni, São Tomé, Tanzania, Thailand, Uganda, Vietnam, and Zambia (Table 1).

Genome sequencing revealed that HeV strains isolated from equine and human sources during the outbreak in Brisbane are identical and differ only little from HeV strains isolated from flying foxes 2 years later. Subsequent sequencing of several additional horse and human HeV isolates confirmed the high genetic similarity. Similar observations were made in Malaysia between the human isolates from the outbreak and bat isolates several years later. In Bangladesh, four human isolates obtained in 2004 demonstrate significant genetic heterogeneity, suggesting multiple spillovers of NiV from flying foxes into the human population. The NiV sequences detected from human patients in India from 2001 to 2018 were more related to NiV strains from Bangladesh than the strains isolated in Malaysia.

Clinical Features

Henipaviruses display either predominantly respiratory or neurological symptoms depending on the host. In natural infections of horses and young pigs with HeV and NiV, respectively, and in experimental infections of different animals with either virus, respiratory symptoms predominate. Neurological symptoms were also observed in a proportion of HeV-infected horses. For human infection with henipaviruses, the incubation period ranges from 2 to 45 days, but for 90% of patients, the incubation time is two weeks or shorter. Experimental infection of horses, ferrets and non-human primates is usually fatal, with death or euthanasia occurring 5–10 days post infection. However, observation following natural infection of horses during the initial outbreak indicated that some animals displayed respiratory symptoms but they survived.

HeV-induced respiratory disease in horses may be accompanied by facial swelling and ataxia and in extremis, a copious frothy nasal discharge. The first two patients infected with HeV presented with fever, myalgia, headaches, lethargy, and vertigo. While one recovered, the other patient developed pneumonitis, respiratory failure, renal failure, and arterial thrombosis, and died of cardiac arrest. Findings at autopsy were consistent with a disseminated viral infection in various organs.

Natural infection of pigs with NiV is usually asymptomatic, an outcome also observed after experimental administration of NiV by the ocular and oronasal route. When symptoms are present, they vary according to the age of the pig. Young animals present primarily with respiratory symptoms. Older animals display increased salivation and nasal discharge and occasionally develop neurological signs such as trembling, muscle spasms, and an uncoordinated gait. In Malaysia, pigs displaying symptoms of NiV infection, such as nasal discharge and rapid and labored respiration, had a harsh and nonproductive cough, which gave rise to the name 'barking-pig-disease'.

In contrast, NiV infection in humans is usually associated with a severe acute encephalitis and although a proportion of cases presented with respiratory symptoms, particularly in Bangladesh, the majority of the patients displayed fever, headache, drowsiness, dizziness, myalgia, vomiting, and a reduced level of consciousness. Clinical signs such as the absence of reflexes and the irregular twitching of muscles or parts of muscles and an abnormal doll's eye reflex are indicative of brainstem and upper cervical spinal cord dysfunction. In the Malaysian outbreak, 105 of 256 patients died, a mortality rate of 41%. However, this figure is reduced to 30% when individuals who experienced either a mild or asymptomatic infection are considered. In Bangladesh, a combined case-fatality rate of multiple outbreaks is approximately 70%. For the most recent NiV outbreak in Kerala, India in 2018, the case-fatality rate was 94%.

Both HeV and NiV can cause prolonged infection in humans before manifesting with severe neurological symptoms. In Malaysia, NiV persisted in a proportion of patients (c. 10%) who either recovered from encephalitis or who had experienced an asymptomatic infection. Such cases of relapsed and late-onset encephalitis, respectively, presented from months to years after the initial infection, with the longest reported case 11 years after an initial acute infection. In relapsed cases, although serum anti-NiV IgG antibody levels were elevated, no IgM response or vasculitis was observed, and no live virus was isolated from the throat and nasal secretions. Only four cases of human HeV infection have been recorded. Two displayed influenza-like symptoms and one died. A third, fatal case of encephalitis occurred over a year after a self-limiting episode of meningitis, attributed to HeV infection.

Pathogenesis

As stated above, data from clinical and pathological studies of human cases as well as animal infection and cell tropism experiments all indicate that the initial site of replication is in the respiratory system. The respiratory disease caused by HeV in horses is characterized by pulmonary edema and congestion. Viral antigen is found in endothelial cells in a range of organs including the lungs, lymph nodes, kidneys, spleen, bladder, and meninges, and virus can be recovered from several internal organs, including the lungs, and from saliva and urine. Young pigs infected with NiV present primarily with respiratory symptoms characterized by tracheitis and bronchial and interstitial pneumonia. After experimental infection by the ocular and oronasal routes, virus replication occurs in the oropharynx and spreads to the respiratory tract and lymphoid tissues before appearing in the trigeminal ganglion and neural tissue. Viral antigen is found, particularly in clinically affected animals, in both lungs and meninges and virus is recovered from a range of tissues including tonsil, nasal, and throat swabs and lungs.

The outcome of henipavirus infections can range from high mortality, as seen with HeV in horses and NiV in humans, to low mortality and morbidity, best exemplified by NiV infection in pigs, to asymptomatic infection in flying foxes. Experimental infections reveal that henipaviruses are infectious following either oronasal or parenteral administration. Figures for the minimum lethal dose of henipaviruses suggest that 200–300 plaque-forming units (pfu) is sufficient to produce a productive infection in some animal models.

Transmission is mostly via the oronasal route. Infectious NiV was recovered from urine and the tracheal and nasopharyngeal secretions of infected patients in the early phases of their illness in the original Malaysian outbreak. However, human-to-human transmission in the Malaysian outbreak was extremely limited. In contrast, human-to-human transmission in Bangladesh has been well documented, probably due to more frequent and closer contact with familial caretakers and religious personnel.

As stated above, henipaviruses are uncommon amongst the paramyxoviruses in respect to their broad host range. The ability to replicate, spread, and cause acutely lethal disease amongst multiple species suggest that these viruses, in addition of using a highly conserved molecules as entry receptor, have evolved effective means to antagonize or evade innate antiviral responses of evolutionally distant hosts from bats, horses, pigs to humans. As in other paramyxoviruses, the major anti-interferon (IFN) defences are encoded by the P gene of henipaviruses. It has been shown that the V, W and C proteins produced from the henipavirus P genes all play a role in modulating host immune system by directly interacting with multiple innate immune signaling molecules, including, MDA5, RIG-I, and TRIM25 which regulate IFN gene expression and STATs which are involved in IFN signaling. Interestingly, the NiV M protein has also been shown to inhibit type I IFN induction by indirectly antagonizing the activity of IKK ϵ , one of the kinases responsible for IRF-3 activation. In this context, it is worth noting that CedV lacks the editing site in the P gene and the virus does not produce the V protein and fail to cause any overt disease in ferrets and guinea pigs, in which both HeV and NiV infection can lead to a severe disease.

In susceptible non-pteropid species, henipaviruses elicit strong humoral immune responses. Antibodies to P, N, and M proteins are evident in Western blots and anti-F and anti-G/RBP antibodies are readily detected by various immunological methods. In

contrast to a consistent antibody response in susceptible, nonvolant species, in flying foxes there appears to be less direct correlation between detectable virus replication and the appearance of antiviral antibodies. Antibody production is irregular and of uncertain longevity. Anti-NiV antibodies were present in most patients with clinical NiV encephalitis and IgM antibodies occurred more frequently than IgG antibodies in both serum and cerebrospinal fluid (CSF). The appearance of specific IgM antibodies in serum preceded their appearance in the CSF, a sequence consistent with virus replicating in primary infection site(s) prior to invasion into the central nervous system.

The role played by cellular immunity in henipavirus infection is less known. In the most recent NiV outbreak in Kerala, careful analysis of humoral and cellular immune responses in the 2 survivors revealed that there was a dramatic increase in activated (Ki67⁺) CD8⁺ T cells with an acute effector phenotype (CD38⁺/HLA-DR⁺/Granzyme B⁺/PD1⁺), suggesting that virus-specific naïve T cells were actively proliferating in response to the infection. It is interesting to note that clearance of viremia coincided with the peak of proliferating Ki67⁺ CD8⁺ T cells, which occurred before the peak IgG antibody levels.

Diagnosis

Traditional diagnostic methods such as virus isolation, EM, immuno-EM, immunohistochemistry (IHC), serology, and polymerase chain reaction (PCR) played key roles in the initial discovery of HeV and NiV.

As henipaviruses are BSL4 agents, it is important to note that while initial attempts to culture suspected henipaviruses may be conducted in a BSL3 laboratory, it is essential to continue further characterization inside a BSL4 facility once a cytopathic effect (CPE) is observed and the growth of henipavirus is confirmed by PCR or immune staining. All henipaviruses can replicate in different cell lines – a feature that contributed to the efficiency with which they were isolated during the initial disease outbreak investigations, but Vero cells remains the most commonly used cell line for initial virus isolation trials. More recently, different bat cell lines have been used with some success.

For molecular diagnosis, PCR is still the method of choice. With the discovery of greater genetic diversity of henipaviruses in different parts of the world, and current PCR tests may not work for unknown viruses, next generation sequencing (NGS) is starting to be employed for outbreak investigation with suspected of henipaviruses or henipa-related viruses as well to any previously unknown pathogens. A probe-based NGS containing hybridization baits covering all known henipavirus genomes has recently been developed for more efficient NGS characterization, especially from clinical samples where host genetic materials are expected to give very background signal masking the low level of virus-specific NGS reads.

For henipaviruses, serologic tests are important both during outbreak investigation and for disease surveillance. The virus neutralization test (VNT) is accepted as the standard reference method. Few laboratories, however, can conduct neutralization tests because of the requirement to handle live virus at BSL4. Two surrogate VNT test platforms which do not require BSL4 containment have been developed: (1) Luminex bead-based test: recombinant soluble G/RBP proteins of HeV or NiV are coated on Luminex beads and the binding of a soluble ephrin-B2 protein is used to mimic the virus-receptor interaction. When neutralizing antibodies are present, they will block this G-ephrin-B2 interaction, thus acting as a surrogate VNT; (2) Pseudotype virus: different pseudotype systems, based on Vesicular stomatitis or lentivirus, carrying the henipavirus F and G/RBP proteins have been developed as a surrogate VNT for detecting henipavirus-specific antibodies. Incorporation of reporter genes in these systems have resulted in a greater sensitivity and reproducibility.

Treatment

At the present time, there is no licenced treatment available for henipavirus infections. Ribavirin, which inhibits the replication of HeV *in vitro*, was used during the NiV outbreak in Malaysia in 1998 and HeV outbreak in 2008 in Australia. While the trial in Malaysia demonstrated a 35% reduction ($P = 0.011$) in mortality, it had no detectable therapeutic effect on the two HeV patients in Australia. In the absence of other therapies, ribavirin may be an option for the treatment of henipavirus infections with patient consent, but the efficacy of ribavirin as a therapy or prophylaxis in people remains uncertain at best. In different animal models, ribavirin either delayed but did not prevent the death or had no effect on infection caused by NiV or HeV.

Chloroquine, an antimalarial drug, was shown to block the critical proteolytic processing needed for HeV F maturation and function. Although the drug inhibited NiV and HeV infection *in vitro*, it did not show any apparent clinical benefit *in vivo*.

In contrast to existing small molecule antivirals, a henipavirus-specific therapeutic heptad peptide-based fusion inhibitor, analogous to the HIV-1-specific enfuvirtide (Fuzeon), has shown promising efficacy in animal studies. The α -helical heptad repeat (HR) domain of henipavirus F1 glycoprotein resembles other fusion glycoproteins which play a role the formation of a trimer-of-hairpins structure during the membrane fusion and virus infection process. In a hamster model of NiV infection, the administration of cholesterol tagged HR-derived peptides provided the first evidence of *in vivo* effectiveness of a fusion inhibiting peptide against NiV.

Finally, passive immunotherapy based on recombinant human monoclonal antibodies to the henipavirus G/RBP protein also appear to have a promising therapeutic potential. In particular, the m102.4 mAb is shown to be effective in a non-human primate model against HeV or NiV infection. While human clinical application is yet to be proven, a phase I clinical trial has been completed, demonstrating the safety for human applications and an effective half-life in humans. The mAb has also been used in

humans with high risk exposure to henipaviruses under emergency and compassionate grounds with no severe side effects observed.

Prevention

A number of promising strategies to develop henipavirus vaccines are being explored. NiV F and G/RBP glycoproteins, either delivered via viral vectors or by administration as purified proteins with adjuvant, elicit neutralizing antibodies in many different animal models.

The most studied and tested vaccine is based on the HeV-sG protein produced in CHO cells. The vaccine was licensed by Zoetis™ Inc., (formerly Pfizer Animal Health) and developed as an equine vaccine, under the trade name Equivac® HeV, for use in Australia. This remains to be the first and only licensed vaccine for any BSL4 agent. The vaccine is 100% effective in protecting horses under experimental challenge studies. Since the vaccine release in 2012, laboratory confirmed HeV infections in horses have only occurred in unvaccinated horses.

NiV is one of the first three high priority targets set by the Coalition for Epidemic Preparedness Innovations (CEPI). Currently there are two CEPI-funded NiV vaccine projects ready for phase I clinical trial: the US-led HeV-sG vaccine platform (an extension of Equivac® HeV to NiV infection in humans) and the Japan-led measles viral delivery platform. Human phase I trials will be completed in the next few years and we are confident that a licenced human henipavirus vaccine will be available thereafter.

Glossary

Antibody prevalence The percentage of a population with antibodies against a certain disease at a given time.

Aplastic anemia Disease characterized by a decrease in blood cells resulting from underproduction due to bone marrow failure; called also hypoplastic anemia.

COPII Coat protein complex II.

cre Cis-acting replication element.

ERGIG ER-Golgi intermediate compartment.

Exosome Vesicle (50–120 nm) released from cells by fusion of late endosomal multivesicular bodies with the plasma membrane that contain various biologically active proteins and RNAs.

Incidence The rate of occurrence of new cases of a particular disease in a population in a certain period of time.

Leukocytopenia Decrease in the number of white blood cells.

Polyprotein processing Cascade of proteolytic cleavage events resulting in release of biologically active intermediate and finally mature proteins from the polyprotein.

Ribosome stalling Transient translation stop.

Serine-like protease Proteolytic enzyme characterized by a catalytic triad similar to that in serine-type proteases with Ser, His, Asp.

History

Jaundice has been known as an epidemic disease for centuries, but the earliest outbreaks of what was almost certainly hepatitis A were documented by Rayrun "MRWmats_scpger, occurring in Preßburg, now Slovakia, in 1674 and 1697. Besides sporadic occurrence of the disease, characterized by a slow increase and slow decrease of the number of infected persons in the course of months (spread by person-to-person contact), with an overall small number of infections, larger vehement epidemics (spread by contaminated water and food) were reported in later times. The first pandemic HAV wave occurred in the 1860s and the first considerable record of the disease was registered during the American Civil War.

In the second half of the nineteenth century, the disease became known as "icterus catarrhalis" (catarrhal jaundice; inflammation of the biliary tract was supposed) or "icterus epidemicus" (epidemic jaundice) as well as campaign jaundice, as epidemics are common in military medical history.

At the turn of the nineteenth to the twentieth century, the disease was recognized as infectious and transmissible by person-to-person contact. The terms "hepatitis epidemica" (epidemic hepatitis) and "hepatitis infectiosa" (infectious hepatitis) were introduced as synonyms for catarrhal jaundice.

Detailed epidemiologic recordings have been conducted since the beginning of the twentieth century. Two large pandemic waves were observed during the twentieth century, the first one originating during World War I and reaching its summit between 1918 and 1922, and the second one originating in the early 1930s reaching its widest distribution with the beginning of World War II.

During World War II, hepatitis was demonstrated to be caused by at least two separate filterable agents, and the resulting diseases were called hepatitis A (infectious hepatitis) and hepatitis B (serum hepatitis), and the etiological agents hepatitis A virus (HAV) and hepatitis B virus (HBV), respectively. We now know three more viruses that have a specific tropism for the liver: HCV, HDV and HEV. These five viruses share no taxonomic and virological relationship.

After World War II, epidemiologic studies in human volunteers showed that hepatitis A is spread by the fecal–oral route, and provided information on the duration of viremia and shedding of virus in feces. In the late 1960s and early 1970s, it was shown that chimpanzees and several small, non-human primates could serve as animal models for human hepatitis A. Meanwhile, mice genetically deficient for *Ifnar1*, a component of the type 1 interferon receptor, or for the mitochondrial antiviral signaling protein (*Mavs*) or the interferon regulatory factors (*Irf3/Irf7*), which are components of the induction pathway for interferon expression, as well as chimeric mice with human liver cells were found to be infectable by HAV and are also used as models for the disease. The replication of HAV in cell cultures was established between 1979 and 1981.

The etiologic agent was identified through immune electron microscopy by Feinstone *et al.* in 1973.

The molecular cloning of the HAV genome in the 1980s revealed that the genomic organization of HAV is similar to that of picornaviruses, and the first infectious cDNA clone of HAV was reported by Cohen *et al.* in 1987.

The disease manifestations by hepatocellular destruction could be attributed to an immunopathogenic mechanism in the late 1980s by Vallbracht *et al.*

An inactivated HAV vaccine has been available since 1992.

Taxonomy and Evolutionary Origin

HAV is a member of the genus *Hepatovirus* within the family *Picornaviridae*.

All human HAV strains known belong to only one serological group, but nucleotide sequence analysis of the VP1-2A junction region and the VP1 coding region, respectively, revealed that several distinct HAV genotypes (seven in the case of VP1-2A junction analysis, six in the case of VP1 region analysis; more than 15% nucleotide variation), which include several subgenotypes (nucleotide variation of more than 7.5%), can be distinguished. These genotypes correlate with the geographic origin of the virus isolates. Genotypes I and III are the most common types worldwide, particularly genotype IA. The cell culture-adapted viruses most commonly used are variants of the Australian strain HM175 (genotype IB) and the German strain GBM (genotype IA).

Recently, multiple novel species, which have the same unique properties as human HAV, have been identified in bats and other small mammals, seals and even marsupials. Phylogenetic analyses indicate that these viruses have frequently jumped between the host species, and ancestral reconstructions suggest that human HAV descended from rodent viruses, which have originated in small insectivorous mammals. Based on the unique capsid structure of HAV, the HAV-like viruses of ancient insectivores might be direct descendants from a picornavirus-like insect virus.

Morphology and Physicochemical Properties

The infectious spherical virion shed in feces is a nonenveloped particle with a diameter of approx. 27 nm. The pentakisdecagonal capsid, which embodies the viral RNA genome, contains 60 copies of each of the 4 structural proteins, VP1 (also known as 1D), VP2 (1B), VP3 (1C) and VP4 (1A) (see [Table 1](#)). The mature capsid has a different structure than other mammalian picornaviruses, as the canyon surrounding the 5-fold symmetry axes, which is a prominent feature of picornaviruses and represents the attachment site to cellular receptors, is missing, and VP2 extends N-terminally across the 2-fold symmetry axis to the adjacent protomer, a feature seen in picornavirus-like dicistroviruses of insects. HAV forms a single serotype and the antigenic structure of the capsid is conserved among the human and the non-primate viruses. In blood as well as in supernatants of infected cell cultures HAV appears enveloped in exosome-like vesicles (eHAV). These vesicles may enclose up to four infectious virus particles, which still contain uncleaved VP1-2A.

The HAV particle has a buoyant density of approx. 1.33 g cm^{-3} in CsCl (in iodixanol of approx. 1.22 g cm^{-3} ; eHAV particles band at approx. 1.08 g cm^{-3} in iodixanol gradients) and a sedimentation coefficient of approx. 160S. Empty capsids found in feces have a sedimentation constant of about 70S. HAV is extremely resistant to acid (pH 1.0 for 2 h at room temperature) and thermal inactivation (60°C for 1 h). The isoelectric point of HAV is between values of 2.8 and 5.8.

Genome Organization and Expression, Replication, Morphogenesis

The linear, single-stranded, positive-sense RNA genome of HAV is approx. 7500 nucleotides in length and is not capped but covalently linked by a tyrosine- O^4 -phospho-diester bond to the 2.5 kDa viral protein 3B (also known as VPg; see [Table 1](#)). It encompasses a structurally complex 5' nontranslated region (NTR) of approx. 740 bases, followed by a single open reading frame encoding a polyprotein (approx. 250 kDa; approx. 2230 amino acids) and a 3' NTR of approx. 60 bases which terminates with a poly(A) tail of about 60 nucleotides. In the polyprotein, the capsid proteins and those with functions during virion assembly represent the N-terminal third (VP4, VP2, VP3, VP1 (numbered according to molecular mass and also known as P1 region), and 2A) (see [Table 1](#) and [Fig. 1](#)) with the remainder of the polyprotein comprising a series of proteins required for RNA replication (2B and 2C followed by 3A to 3D) (see [Table 1](#) and [Fig. 1](#)).

The viral polyprotein is translated directly from the messenger-sense genomic RNA, which is released into the cellular cytoplasm after uncoating of the virion. An internal ribosomal entry site (IRES) located within the 5' NTR (see [Table 1](#)) is involved in the cap-independent initiation of protein synthesis. The IRES of HAV differs from that of other picornaviruses and forms its own group (type III picornavirus IRES). Translation from the HAV IRES requires all of the initiation proteins, including eIF4E and intact eIF4G, and infection with HAV does not result in cleavage of the translation initiation factor eIF4G to block the cap-dependent host protein synthesis, as featured by other picornaviruses. The HAV IRES-directed initiation of translation, which depends on the entire 5' NTR, is enhanced by sequences of the 5'-terminal coding region and by certain host cell factors, e.g., glyceraldehyd 3-phosphate dehydrogenase, poly(C) binding protein and polypyrimidine tract binding protein. The efficiency of translation is decreased by an extraordinarily high proportion of rare codons (particularly in the P1 coding region). But, as HAV does not induce shutdown of cellular protein synthesis, this not optimal codon usage might avoid strong competition for tRNAs and in addition may support proper protein folding by ribosome stalling. A further characteristic of the genome is a low G/C ratio and the avoidance of CpG dinucleotides.

Proteolytic processing of the primary polyprotein (see [Fig. 1](#)) occurs simultaneously with translation and is largely carried out by the viral 3C protease, which is a serine-like protease in which cysteine replaces the nucleophilic serine in the catalytic triad of the active center. As cellular substrate, PABP (poly(A) binding protein) has been described for mature 3C, obviously resulting in late negative regulation of translation and contributing to the switch to replication. Furthermore, processing intermediates of 3C, in this case 3ABC and possibly 3CD, interfere with the induction of IFN- β transcription by 3C-mediated cleavage of MAVS (mitochondrial antiviral signaling protein), and of TRIF (TIR domain-containing adaptor inducing IFN- β), respectively (see [Fig. 3](#)).

Table 1 HAV regulatory genomic regions and HAV proteins; all numbering refers to HAV strain HM175 (accession no. NC_001489).

<i>Regions/Proteins</i>	<i>Nucleotide position</i>	<i>Length in amino acids</i>	<i>Proposed or known function</i>	<i>Remarks</i>
5' nontranslated region (5' NTR)	1–734	–	5' stem-loop region (nucleotides 1–94): required for RNA replication Polypyrimidine tract pY1 (nucleotides 99–138): unknown function Internal ribosomal entry site (IRES) (nucleotides 152–734): directs cap-independent initiation of translation Involved in regulation of RNA replication	Mechanisms regulating switch from translation to replication are not clear Picornaviral Type III IRES
3' nontranslated region (3' NTR)	7416–7478	–		
1A	735–803	23	Extended by 40–80 adenylates Capsid protein VP4 Morphogenesis Pore-forming activity: may facilitate release of genome from the capsid	Involvement in translation is not clear Not myristoylated
1B	804–1469	222	Capsid protein VP2	During morphogenesis, precursor VP4 - VP2 (VP0) is likely cleaved autocatalytically

1D	2208–3023/ 3026/3029	272/273/274	Capsid protein VP1	
				Heterogeneous C terminus, depending on HAV strain and host cell
				During morphogenesis, precursor VP1–2A (also known as VP1pX), is likely cleaved by cellular protease So far not identified in infected cells
2A	3024/3027/ 3030–3242	71/72/73	Morphogenesis	
2B	3243–3995	251	Structural rearrangements of intracellular membranes for replication	Peripheral association with membranes Influence on membrane permeability Induces structural alterations of the ERGIC structure Mutations accompany adaptation to growth in cell culture Interferes with induction of beta interferon transcription by an unknown mechanism (affects MAVS and the IRF-3 kinases)
2C	3996–5000	335	Structural rearrangements of intracellular membranes for replication	Integral association with membranes Mutations accompany adaptation to growth in cell culture Interferes with cellular macromolecular synthesis
3A	5001–5222	74	As 3AB VPg precursor(pre-VPg)	Interacts with membranes, may anchor pre-VPg to cellular membranes through a central region of 21 hydrophobic amino acids Induces structural alterations of intracellular membranes Tyr ³ attached to 5' terminus of genomic RNA
3B	5223–5291	23	VPg (virus protein genomic) Supposed protein primer for RNA replication	
3C	5292–5948	219	Sole protease	Serine-like protease, with replacement of Ser by Cys in catalytic triad: Cys ¹⁷² , His ⁴⁴ , Asp ⁸ Involved in switching viral translation to replication by cleavage of PABP Intermediate 3ABC interferes with induction of beta interferon transcription by cleavage of MAVS
3D	5949–7415	489	RNA-dependent RNA polymerase	Interferes with cellular COPII-mediated, classical secretory pathway cre-element consisting of 110 nucleotides with conserved AAACG motif at 5' coding region required for replication: template for VPg (3B) uridylation

Fig. 1 HAV genomic RNA and HAV polyprotein processing including known or supposed functions of the viral proteins during morphogenesis and replication. The polyprotein that results from IRES-directed translation is cleaved by the viral protease 3C to release certain precursor proteins with biologically relevant functions as well as the mature nonstructural proteins. Primary cleavage results in the release of the structural precursor VP4-VP2-VP3-VP1-2A, which associate to assembly intermediates (pentamers), which are stabilized by 3C cleavage of the VP3 junctions (VP4-VP2 (VP0), VP3, VP1-2A)₅. After assembly of the intermediate protein building blocks and the viral genome to provirions, maturation cleavages occur through an unknown proteolytic activity to release VP4 from VP2 and through a cellular, presumably a lysosomal protease to release 2A from VP1, resulting in the infective virion with 60 copies of each of the main structural proteins VP1 to VP4.

Synthesis of viral RNA by the viral 3D polymerase follows the accumulation of the nonstructural proteins spanning 2B to 3D, which induce the assembly of a macromolecular replication complex on membranes that are recruited from intracellular membranes. It is not clear which cellular membranes and which viral proteins are involved in this process. But it was demonstrated that the proteins 2B, 2C, 3A, 3B and their processing intermediates are able to interact with intracellular membranes and to induce structural membrane rearrangements. RNA transcription is protein-primed, with the uridylylated VPg protein 3B (VPg-pUpU), which is produced in a reaction templated by a cis-acting replication element (*cre*) in the 5'-terminal coding region of 3D, representing the primer for the negative-sense RNA replication intermediate and the subsequent positive-sense genomic RNA synthesis. A participation of the 5'-terminal NTR structures in the switch from translation to replication on the same viral RNA is suggested.

HAV morphogenesis is poorly understood. The primary polyprotein cleavage event occurs at the 2A/2B junction mediated by the 3C protease resulting in the structural precursor P1-2A. The steps resulting in particle formation are not entirely clear, but a model for this process has been suggested (see Fig. 1). The P1-2A structural precursors assemble to a pentameric structure and are further cleaved by the 3C protease to generate the precursors VP4-VP2 (also known as VP0) and VP1-2A (also known as VP1pX), as well as VP3 resulting in a structural building block (VP0,VP3,VP1-2A)₅. The 2A C-terminal extension of VP1 is a critical structural intermediate in virion morphogenesis, probably clamping the pentamer at the fivefold symmetry axis. After assembly of 12 such pentamers with the genomic RNA to provirions (12 × (VP0,VP3,VP1-2A)₅-RNA), VP0 is cleaved into VP4 and VP2 by an unknown mechanism. These immature particles, still containing VP1-2A, are present in lysosome-like vesicles as well as in multivesicular

bodies (MVB). Entry into MVBs is supposed to be mediated by an interaction between VP2 and the cellular endosomal sorting complex required for transport (ESCRT) and from there still immature HAV is secreted non-lytically in exosome-like vesicles (eHAV) from the basolateral site of hepatocytes into blood. How immature particles get access to lysosome-like vesicles is unknown, but the maturation cleavage at the VP1-2A junction leading to the removal of 2A seems to result from the action of a lysosomal protease before mature HAV virions are apically released into bile non-lytically via a secretory lysosomal pathway.

Host Range, Transmission and Tissue Tropism

Until recently, when several HAV species were discovered in diverse mammals, only humans and certain species of non-human primates were considered to be infectable by HAV under natural conditions. Non-human primates, which are also used as animal models, include chimpanzees, marmosets and owl monkeys. As mice with an impaired interferon system become permissive to human HAV infection, the ability of HAV to interfere with the species-specific interferon system (e.g., cleavage of MAVS) seems to contribute to HAV's host tropism.

HAV is transmitted via the fecal-oral route. As the virus is excreted in feces, it is typically acquired by ingestion of feces-contaminated food or water. Direct person-to-person spread occurs under poor hygienic conditions.

The site of HAV replication is the liver. The events that occur during the passage of HAV across the intestinal epithelium into blood, in which the virus reaches the liver via the portal circulation, are not clearly understood. Although HAV antigen could be detected in different organs, such as the kidneys, spleen and gastrointestinal tract, no extrahepatic sites of HAV replication have been clearly identified. The only evidence for replication within the gut comes from studies of orally inoculated owl monkeys, but it was demonstrated that replication of HAV in polarized intestinal cells does not result in basolateral release of the virus progeny and thereby not in penetration of the epithelium.

A functional cellular receptor could not be identified so far. The ubiquitously expressed cell surface T cell immunoglobulin mucin 1 (TIM1) protein, which binds HAV and had been suspected to be a HAV receptor (also known as HAV_{cr1}), is not essential for cellular entry. It can be supposed that the HAV receptor is expressed by different cell types, and conserved through evolution, and it is unlikely that the receptor is the main determinant of the strong hepatotropism. Some studies suggest that the hepatotropism of HAV is supported by fecal immunoglobulin A (IgA)-virus complexes (HAV/IgA), as HAV-specific IgA facilitates transcytosis of virus particles antivectionally through polarized epithelial cells via the polymeric immunoglobulin receptor (pIgR), and as subsequently HAV/IgA uptake via the hepatocellular asialoglycoprotein receptor (ASGPR) results in infection of hepatocytes (IgA-carrier hypothesis).

As for eHAV, which is released into blood but not into the fecal transmission pathway, it is unknown how it enters hepatocytes and that selectively. The entry of eHAV might occur via an endocytotic pathway in which the virus is amenable to HAV-specific neutralizing antibodies, which develop in the course of the infection.

After entry of HAV into susceptible cells, the structural protein VP4 might facilitate the release of the genomic RNA into the cytoplasm by its pore-forming ability (pores of 5–9 nm in diameter) in endosome-like membranes at acidic pH.

The virus progeny produced in the liver is released back into the intestinal tract via bile for transmission.

Cell Culture and Growth Characteristics

In vitro HAV can infect a variety of primate and nonprimate cell lines, including nonhepatic cells. The virus exhibits a protracted replication cycle and normally establishes a noncytolytic, persistent infection with low virus yields, and there is no evidence that HAV notably interferes with the macromolecular synthesis of the host cell. After infection of cultivated cells with the wild-type virus, a minimum of 8 weeks elapses before HAV can be isolated. Although a more rapid replication and higher virus titers are obtained after serial virus passages in cultivated cells resulting in cell culture-adapted viruses, even the replication of these virus variants is not detectable within the first days after infection. Adaptation of HAV to growth in cultivated cells seems to be achieved by varying sets of multiple interacting mutations, with adaptive mutations within the IRES enhancing viral translation in a cell-type-specific fashion, and mutations clustering in the 2B and 2C proteins (see [Table 1](#)) increasing replication regardless of the cell line used.

The virus apparently downregulates its own replication and this may, for example by supporting the ability of HAV to inhibit innate cellular anti-viral defense mechanisms, be important for the establishment of persistent infections. A large proportion of the virus progeny remains cell associated, but extensive release of HAV and eHAV from the cells also occurs.

Several cytopathogenic variants of HAV have been isolated which induce apoptosis resulting in cell death. These variants are highly cell culture adapted and characterized by a rapid replication phenotype and high virus yields. In these variants, both the downregulation of viral replication and the ability to inhibit the innate defense mechanisms are less effective. The molecular mechanisms resulting in apoptosis are not known.

Clinical Features and Pathology

HAV infection may lead to a wide spectrum of manifestations ranging from a silent infection, over icteric courses to a fatal fulminant hepatitis. The acute icteric course of infection varies between common, over prolonged to relapsing hepatitis A. Persistent infections or chronic disease states have not been described.

The clinical presentation of the disease depends on the age of the infected individual. The likelihood of having symptoms and the severity of the disease increases with the age of the patient. Silent infections (asymptomatic or at least anicteric) are normally observed in very young children, under the age of 2. However, a clinically detectable disease can occur even in infancy (aged 2 weeks to 8 months) and it may be characterized by prolonged courses. In children under 5 years of age approximately 3%, in children 5–15 years old approximately 30% and in individuals over the age of 18 years as many as 70% may develop a clinically detectable disease.

The heterogenous outcome of HAV infections seems to depend on individual physiological conditions and multiple independent factors, such as the amount of virus progeny, the strength of IgA and IgG responses or the activity of the cytotoxic T lymphocytes.

Common Course of Infection

The incubation period ranges from 2 to 6 weeks with a mean duration of 4 weeks. The prodromal (preicteric) period of normally 4–6 days (which may vary from 1 day to more than 2 weeks) is characterized by nonspecific symptoms, like anorexia, nausea with vomiting, malaise, abdominal pain, loss of appetite, accelerated pulse, rash, headache and fever (38–39°C) as well as by gastrointestinal symptoms, typically as obstipation, but diarrhea is also observed.

The prodromal symptoms disappear with the onset of jaundice, which is seldom abrupt (in 15% of the cases no obvious prodromal symptoms are observed before the appearance of jaundice). The icteric phase, which ranges from 2 to more than 22 days (mean duration 3 weeks), is marked by jaundice, which may start with scleral icterus, dark-colored urine (conjugated bilirubinuria), clay-colored stools and clearly decelerated pulse.

The reconvalescence period ranges from 3 to 6 weeks, but fatigue, dullness, right upper quadrant tenderness and fast exhaustion may remain for 2–4 months. In almost all cases the liver is enlarged.

The clinical symptoms are accompanied by several abnormal biochemical parameters (see Fig. 2). The elevation of aminotransferase levels in serum (alanine aminotransferase (ALT) and to a lesser degree aspartate aminotransferase (AST)), which reflect hepatocellular damage with the release of liver enzymes into the circulation, roughly correlate with the severity of the disease. The elevation of serum alkaline phosphatase activity and serum bilirubin level relate to intrahepatic cholestasis.

At the onset of symptoms, seroconversion to HAV occurs.

Large amounts of HAV, which are produced in the liver and released into the gastrointestinal tract via bile, are secreted in the feces already during the late incubation period when no clinical symptoms are detectable and are shed for approximately 3 weeks until a few days after the onset of elevated levels of liver enzymes in the serum (see Fig. 2). Fecal shedding of HAV reaches its maximum just before the onset of hepatocellular injury and terminates around the time when the IgG antibody response is detectable.

Viremia occurs a few days before and during the early acute stage of the clinical and biochemical hepatitis, in which it roughly parallels the shedding of virus in feces, but at a lower magnitude (see Fig. 2).

More sensitive methods (especially nucleic acid amplification technologies) demonstrated that low levels of viral RNA may be present in feces and blood for many weeks.

Prolonged Hepatitis A

In 8.5%–15% of the cases, jaundice lasts for up to 17 weeks. In general, the symptoms are initially stronger than during the common course of the infection and the antibody titers reached are higher and sustain for a longer period of time. Virus in feces and blood may be detectable for 2–3 months. The biochemical abnormalities last at least 5 months. Occasionally, prolonged courses are accompanied by exceptionally high serum aminotransferase levels (ALT up to 560 IU dl⁻¹) and by high serum bilirubin levels (up to 7.4 mg dl⁻¹) persisting for months (cholestatic hepatitis A). The cholestatic form of HAV infection is associated with extensive itching of the skin.

The pathogenesis of prolonged hepatitis is not understood and different factors could contribute to the extended course: reinfections at different sites of the liver may occur by enterohepatic cycling of HAV, which may be supported by anti-HAV immunoglobulin A (IgA) (IgA-carrier hypothesis) and by serum eHAV (enveloped HAV), respectively. HAV/IgA is neutralized for infection of hepatocytes via the ASGPR only late in the course of infection by highly avid immunoglobulin G (IgG) and eHAV is resistant to neutralizing antibodies. Membrane enveloping of HAV might also facilitate viral spread in the liver supporting infection for a longer time. Also NF-κB, which is activated by HAV, may contribute to prolonged courses by attenuation of the effects of HAV-specific cytotoxic T cells. Furthermore, infection by different HAV genotypes resulting in an elongated course of the disease has been speculated.

Relapsing Hepatitis A

After initial improvement in symptoms and liver test values (serum aminotransferase levels), one or more relapses of the disease (mostly biphasic) are described for up to 20% of the patients (the average age in adults is 30 years, in children 9 years). These relapses occur between 30 and 90 days after the primary episode, when high titers of neutralizing antibodies are already present. The severity of symptoms, the serum aminotransferase levels and the immunoglobulin M (IgM) response are similar or weaker than observed during the initial phase, with a higher tendency for cholestasis (30% of these patients). The relapses last longer

Fig. 2 Course of clinically relevant events in acute hepatitis A. This figure schematically shows the mean duration and intensity of certain parameters. The dotted lines indicate the duration and intensity of the events that may vary. NK T cells: Natural killer T cells.

(mean duration 6 weeks) than the initial phase, HAV is present in blood and the serum bilirubin level is higher. During the relapse the tendency for purpura and itching of the skin is increased.

No specific risk factors could be identified and the pathogenesis of relapsing hepatitis is not understood. The relapses may represent a manifestation of endogenous reinfections by an enterohepatic cycling of HAV/IgA (IgA-carrier hypothesis) until the reinfection cascade is terminated by competitive replacement of the IgA in the HAV/IgA complexes by large amounts of the avidity-matured IgG response.

Fulminant Hepatitis A

In rare cases, acute hepatitis A results in a fatal deterioration in liver function with massive destruction of liver cells. Surprisingly, no vigorous inflammatory response is observed. The fatality rate is below 1.5% of all hospitalized icteric HAV infection cases. This course of the disease is accompanied with fever over 40°C. This outcome is more frequent in adults, especially in patients over 50 years of age, and the risk is increased in patients with underlying chronic liver disease.

Extrahepatic Manifestations

Extrahepatic manifestations of the disease are rare and the etiology is unclear. Besides frequently observed transient suppression of hematopoiesis (a significant leukocytopenia occurs 1–7 days before the appearance of jaundice correlating with the viremic and the fever phases; see Fig. 2), rare cases of aplastic anemia (occurring 1.5–2 months after appearance of jaundice) with a lethality rate of over 90% are described, and it was demonstrated that HAV infects monocytes and inhibits their further differentiation. In some patients interstitial nephritis, pancreatitis, myocarditis or Guillain-Barré syndrom were observed. By statistical evaluation of medical records, it was suggested that HAV exposure may leave a protective effect on the development of asthma and allergic diseases. However, due to contradictory findings in different studies this is still a subject of debate.

Pathology

The pathology of the liver in acute hepatitis A has been studied in humans and some animal models. The pathological lesions, which are caused by an immunopathogenic mechanism, are characterized by hepatocellular necrosis, which is most prominent in periportal regions, accompanied with large inflammatory infiltrates of mononuclear cells.

Innate and Adaptive Immune Response

Innate Immune Response

HAV, which does not interfere with the replication of other viruses, prevents the synthesis of beta interferon (IFN- β). However, the virus is sensitive to alpha and beta interferon (IFN- α/β) exogenously added to persistently infected cells. It can be demonstrated that HAV inhibits the transcription of the IFN- β gene by blocking effectively interferon regulatory factor 3 (IRF-3) activation due to a cooperative interaction of the HAV proteins 2B and 3ABC with the mitochondrial antiviral signaling protein MAVS, which is a component of the retinoic acid-inducible gene-I (RIG-I) and melanoma differentiation-associated gene 5 (MDA-5) signaling pathway (see Fig. 3). While MAVS is targeted for HAV protease 3C-mediated proteolysis by 3ABC, an intermediate of polyprotein

Fig. 3 Interference of HAV with the interferon system. This figure schematically shows the sites and effects of the interference of hepatitis A virus with IFN induction. The figure also displays that, besides inhibiting protein kinase R (PKR) activity, HAV does neither interfere with interferon signaling nor significantly with cellular macromolecular synthesis. dsRNA, Double-stranded RNA; IFN, Interferon; IRF, Interferon regulatory factor; ISGs, Interferon stimulated genes; ISRE, Interferon stimulated response element; MAVS, Mitochondrial antiviral signaling protein; MDA, Melanoma differentiation-associated gene; OAS, Oligoadenylate synthetase; RIG-I, Retinoic acid-inducible gene I; TLR, Toll-like receptor.

processing localized to mitochondria by 3A, 2B indirectly seems to interfere with MAVS as well as with the kinases responsible for IRF-3 phosphorylation (TBK1/IKK ϵ) through interactions with cellular membrane structures. Signaling through the Toll-like receptor 3 (TLR-3) pathway is also impaired by an interaction with TRIF (TIR domain-containing adaptor inducing IFN- β) (see Fig. 3). Gamma interferon (IFN- γ) produced by HAV-specific HLA-dependent cytotoxic T lymphocytes (CTL) may contribute to the elimination of the HAV infection by inducing an antiviral state in the later stages of the infection. The importance of NK cells for the elimination of HAV is controversially discussed.

As CpG containing codons are avoided in the coding sequence, HAV evades recognition of unmethylated viral CpG by Toll-like receptor 9. Furthermore, it could be shown that HAV inhibits the activity of protein kinase R (PKR) by a so far unknown mechanism (see Fig. 3).

Whether HAV induces or inhibits the activation of NF- κ B is controversially discussed.

HAV also has the ability to prevent apoptosis induced by accumulating dsRNA, but the underlying mechanism is not clear.

Adaptive Immune Response

Anti-HAV IgM antibodies are present in almost all patients at the onset of the symptoms (see Fig. 2). These antibodies reach their maximum level 2 months post exposure, have only weak neutralizing activity and disappear in the course of 3 months, but in the case of prolonged infections IgM can be detected up to 1 year after onset of icterus.

Anti-HAV IgA antibodies are also detectable at the onset of the symptoms (see Fig. 2). This response reaches its peak titer 50 days post infection and may last for more than 5 years. The majority of the IgA remains as serum IgA in circulation and is not secreted into the intestinal tract as secretory IgA by the polymeric immunoglobulin receptor (pIgR) pathway. But a significant fraction of this serum IgA is released into the gastrointestinal lumen via bile by liver functions under participation of the hepatocellular IgA-specific asialoglycoprotein receptor (ASGPR). Fecal samples contain IgA from 5 weeks till 3–6 months post infection. Salivary anti-HAV IgA is also detectable in HAV patients, its course parallels that of fecal IgA. The role of secretory IgA antibodies in the protection against HAV infection appears to be limited, as neutralizing activity is barely detectable. Studies suggest that HAV-specific IgA can serve as a carrier molecule for a liver-directed transport of the virus, supporting and enhancing the hepatotropic infection by uptake of HAV/IgA immunocomplexes via the ASGPR (IgA-carrier hypothesis). As IgA-coated HAV is translocated antiverotically from the apical to the basolateral site of epithelial cells via the pIgR, it was assumed that fecal HAV/IgA immunocomplexes, whose stability enables their fecal-oral transmission, are able to support the primary infection utilizing the IgA receptors. Furthermore, an enterohepatic cycling of HAV may be established during infection by HAV/IgA resulting in endogenous reinfections of the liver until large amounts of highly avid IgG replace IgA in HAV/IgA immunocomplexes. Depending on individual factors, this mechanism may play a role in the development of the different courses of hepatitis A. It is not clear by which processes and mechanisms the induction of the anti-HAV IgA response occurs.

Neutralizing anti-HAV immunoglobulin G (IgG) antibodies are also detectable 3 weeks post infection for the first time, but this response develops slowly, reaching its peak titer approximately 4 months post infection (see Fig. 2), a time point late in the convalescence phase. Envelopment of HAV in blood (viremia) by cellular membranes (eHAV) unrecognizable for the immune system may contribute to the slow IgG antibody response, as well as the transient perturbation of hematopoiesis, which may result in an attenuation and retardation of the inflammatory response and of the induction of the adaptive IgG response. Anti-HAV IgG persists lifelong, although the titer may fall to undetectable levels after several decades. Neutralizing antibodies, which are effective in eliminating the virus from the blood, do recognize a conformational epitope clustered into a major, immunodominant antigenic site involving residues contributed by VP3 (Asp₇₀, Gln₇₄) and VP1 (Ser₁₀₂, Val₁₇₁, Ala₁₇₆, Lys₂₂₁). Neutralization of eHAV by antibodies is possible during an assumed endocytotic re-uptake from blood by hepatocytes in an endosomal compartment.

HAV-specific, HLA-restricted cytotoxic CD8⁺ T-lymphocytes (CTL) accumulate in the liver during the acute phase of the infection (after destruction of the infected hepatocytes, approximately 2–3 weeks after onset of the icterus, the CTLs leave the liver back into blood) and they play a prominent role both in eliminating the virus and in causing a liver injury (see Fig. 2). Gamma interferon (IFN- γ), released by these CTLs, may stimulate HLA class I expression on hepatocytes and in the following promote upregulation of the normally low level display of antigen on liver cells. Multiple dominant T-cell epitopes could be identified in the proteins VP1, VP2, VP3, 2B, 2C and mainly 3D (amino acids 2025–2033). This multitude of T-cell epitopes combined with an inhibitory effect of HAV on CTL-suppressing regulatory T cells (by binding of HAV to HAV_{cr1} expressed on T_{regs}) during the acute phase of the disease seems to result in a strong activity of HAV-specific CTLs. Studies in experimentally infected chimpanzees suggest a more complex T cell response with the involvement of anti-viral cytokines producing CD4⁺ helper T cells also. In addition, NK T cells and possibly bystander-activated CD8⁺ T cells seem to be involved in the elimination of HAV and the destruction of hepatocytes. Therefore, multiple immune mechanisms seem to contribute to the acute liver injury in humans (immunopathogenesis), also leading to an efficient elimination of HAV, which might prevent persistence of the virus.

Diagnosis

Since the clinical presentation of hepatitis A cannot be distinguished from hepatitis caused by the other hepatitis viruses, serologic tests or nucleic acid amplification techniques are necessary for a virus-specific diagnosis.

The routine diagnosis of acute hepatitis A is made by detection of anti-HAV IgM in the serum of patients (see Fig. 2). A further option is the detection of virus in the feces.

In order to improve the safety of blood and blood products, blood screening with HAV-specific polymerase chain reaction (PCR) is performed, which reduces the window period of up to 3 weeks post infection during which HAV infection fails to be diagnosed by serologic assays.

Epidemiology

HAV occurs worldwide and accounts for over 1.5 million clinical cases reported annually. The seroprevalence pattern ranges from high endemicity, such as in Africa, Southern Asia and Latin America, where infection normally occurs in childhood, over intermediate endemicity, such as in Eastern Europe and the northern parts of Asia, to low endemicity, such as in Western Europe and North America, where the majority of the population remains susceptible to HAV infection. However, the epidemiology pattern is complex and continuously changing, with considerable heterogeneity among different countries. In general, the anti-HAV antibody prevalence inversely correlates with the quality of the hygienic standards, and the incidence declines in many populations through improvements in public sanitation and living conditions. These improvements result in an increase of the pool of susceptible adults, with a shift in the age of infection to older age groups, in which a more severe disease form is observed, leading to an increased morbidity. HAV has been recognized as a main cause of fulminant hepatic failure in a growing number of countries.

A minor seasonal variation of HAV infections is observed, with a peak occurring during the fall and winter months, mentioned in almost all earlier and contemporary reports, nowadays possibly as a result of exposure during summer vacations spent in endemic countries.

At special risk for acquisition of hepatitis A are international travelers from areas of low endemicity to endemic areas, employees of child-care centers and sewage plants, gully workers, injecting drug users, homosexually active men and persons with an increased risk of developing a fulminant disease, such as persons with chronic hepatitis C virus (HCV) infections.

The high physical stability of HAV provides a good opportunity for common-source transmission. Community-wide outbreaks are reported in association with infections of food handlers, and linked to contaminated food and drink, or uncooked clams from contaminated water. Hepatitis A is most commonly acquired by sharing the household with an infected person.

Prevention and Control

There is no specific antiviral treatment for hepatitis A. As almost all HAV infections are spread by the fecal-oral route, good personal hygiene, high-quality standards for public water supplies, and proper disposal of sanitary waste are important measures to reduce virus transmission.

Until the availability of an active prophylaxis, the disease could be prevented for up to 5 months with a certainty of 80%–90% by passive immunization with pooled IgG of at least 100 IU anti-HAV antibodies, a prophylaxis which is effective within hours. IgG is still used for postexposure prophylaxis. If administered within 2 weeks after exposure, either development of the disease is prevented or the severity of the disease as well as virus shedding is reduced.

Since 1992, inactivated vaccines for active immunization have been available. These vaccines contain purified, attenuated, formalin-inactivated HAV produced in cell culture, which are absorbed to an aluminum hydroxide adjuvant. They are highly immunogenic and protect against both the infection and the disease caused by all strains of HAV with 100% efficacy for at least 10 years, which is consistent with the finding that all human HAV strains belong to one single serotype. HAV vaccines are also effective when given within 2 weeks after exposure.

Live, attenuated HAV vaccines have been developed in China for a single-dose, subcutaneous injection using virus adapted to grow in cell culture, which protect with similar efficacy as the inactivated vaccines. No reversion of the attenuated virus to virulence has been reported so far. However, viral shedding is possible, which must be taken into account in vaccinations in populations with large numbers of susceptible adults (see Epidemiology section).

Although the minimum level of neutralizing antibodies that protect against infection and disease is unknown, an estimate of a minimal protection level is approximately 20 mIU ml⁻¹ blood.

Glossary

Immunomodulation Changes in the body's immune system, caused by agents that activate or suppress its function.

Nucleos(t)ide analogue Antiviral medication that is incorporated into viral nucleic acid during synthesis causing chain termination.

Perinatal Of, relating to, or being the period around childbirth, especially the five months before and one month after birth.

Percutaneous Through the skin following injury or puncture with a needle.

Quasispecies A population of closely related variants of a virus isolated from an individual at a given time.

Introduction

Since the discovery and recognition of HBV as a human hepatitis causing pathogen, great strides have been made in our understanding of its epidemiology, virology, life cycle, pathogenesis, treatment and vaccine protection. Discovered by Bloomberg and co-workers just over fifty years ago, it remains a major cause of morbidity and mortality in countries of the world where the virus is still endemic, in spite of effective regimens of antiviral drugs which suppress viral replication and vaccine campaigns to protect those at greater risk. Recent estimates suggest that 291 million people are chronically infected with HBV representing a global prevalence of 3.6%–3.9%. Accurate figures of chronic infection are incomplete from many parts of the world and even from Western countries entry data on death certificates for example may not be accurate. Thus there is a reliance on mathematical models that take into account various confounding factors. These suggest that as chronic infection over many years may lead to cirrhosis and hepatocellular carcinoma, the incidence of these two conditions for all viral hepatitis is 1.4 million annually, of which nearly 700,000 are HBV-related. This represents an increase of over 33% over the period 1990–2013, when viral hepatitis climbed from 10th to the 7th position of leading causes of mortality worldwide.

Although, the prevalence of HBV infection is decreasing in several highly endemic countries due to actions which will be explained later, acute infections still occur primarily in high risk populations. What is more, recent population movements and migration from war-torn regions of the world to low endemicity countries may be changing the prevalence and incidence of HBV in these countries, particularly if such individuals evade surveillance. Vaccination programs and antiviral treatment remain the only means of reducing infections and halting progression of chronic liver disease to cirrhosis and HCC respectively.

The study of the life cycle and molecular biology of HBV, in the absence of a reliable cell culture system for the propagation of the virus has been re-invigorated in recent years following the identification of its hepatocyte receptor. Nevertheless, studies in the early 1980s employing genetic engineering techniques led to the cloning of the viral genome and its sequencing. This allowed expression of its proteins, enabling the study of their function, and more importantly, unraveled the unique and fascinating mechanism of its replication strategy. In this respect, the contribution of animal models has been invaluable. These initially employed chimpanzees, and subsequently ducks, woodchucks, transgenic and more recently chimeric mice. This has allowed the study of many aspects of the life cycle, molecular biology and immuno-pathogenesis of the virus, and facilitated vaccine development and antiviral testing. What follows is what we know to-date about this very important pathogen.

Classification

HBV is the prototype member of the *hepadnaviridae* which comprises a group of hepatotropic DNA viruses that have been steadily growing in numbers. These viruses are species specific and are broadly divided into two genera depending on their natural host. Thus, the mammalian *Orthohepadnavirus* genus includes members that infect rodents such as woodchucks (*Marmota monax*) and ground squirrels (*Spermophilus beecheyi*), bats (various species) and primates (humans, chimpanzees, gorillas, gibbons, baboons, orangutans, macaques and woolly monkeys). The *Avihepadnavirus* genus infects birds such as pekin ducks (*Anas domestica*), herons, storks, geese and parrots with about 80% homology between them. The homology between the two genera is around 40% and the genetic relatedness of sequenced isolates from various species are evident in Fig. 1. Three branches are discernible within the orthohepadnaviruses, with human and primate isolates grouping together, and two other groups representing rodent and bat isolates respectively.

Fig. 1 Phylogenetic tree based on complete genome sequences of mammalian, rodent and bat HBV isolates, showing three separate groupings. Human HBV genotypes A-J group together with primate isolates as shown. Similarly, rodent isolates from woodchuck (WHV), ground and arctic squirrel hepatitis virus (GSHV, ASHV) group together. Bat HBV isolates from different species group together on the third branch (e.g., LBHBV, long-fingered bat HBV). Fig. 2 Structure of the hepatitis B virion. (a) Electron micrograph of HBV purified from plasma showing the infectious Dane particle and the spherical and filamentous subviral particles. (b) Cartoon of the virion and its components.

Virion Structure

HBV has pleomorphic appearance under the electron microscope (**Fig. 2**) and this because other than the infectious virions, often referred to as Dane particles, there is an abundance of subviral particles which are known as filaments and spheres. The Dane particles were named after the scientist who led the team that discovered them and have a diameter of 42–45 nm. The virions have an outer glycolipid envelope made of hepatitis B surface antigen (HBsAg) in a lipid bilayer, which is thought to derive from the endoplasmic reticulum membrane. This in turn encloses the nucleocapsid or core of the virus consisting of hepatitis B core antigen (HBcAg) and measuring 30–32 nm in diameter. The cores contain the viral genome and a copy of its polymerase. Additionally the virus produces a soluble protein known as hepatitis B e antigen (HBeAg) which is not a structural protein, but rather constitutes a marker of active viral replication.

The abundant sub-viral particles circulating in serum consist entirely of HBsAg and are devoid of cores and any viral nucleic acid. In this respect, these particles are not infectious. As mentioned above, these are the 25 nm spheres and the 22 nm diameter filaments, which outnumber infectious virions by 100–10,000-fold. Their production and secretion in such excess may serve to mop up anti-HBs antibodies or cause T cell anergy, both of which may contribute to immune tolerance and thus viral persistence. Similarly, HBeAg is thought to function as a tolerogen.

Fig. 3 Genome organization of the virus (a) and the transcripts encoding the various viral proteins (b), synthesized from cccDNA. All of them terminate at the common polyadenylation site. Genome

The partially double stranded DNA viral genome is a relaxed circular molecule (rcDNA) 3.2 kb in length, and is the smallest among DNA viruses. The strands overlap as shown in [Fig. 3](#) with the minus (–)-strand being complete and the positive (+)-strand incomplete at its 3' end and of variable length (about 600 nucleotides missing). It is one of the most compact genomes as it contains 4 wholly or partially overlapping open reading frames (ORFs) ([Fig. 3](#)). What is more, every nucleotide of the genome lies within the coding region of one of the 4 ORFs. These ORFs also incorporate in them all of the regulatory elements of the virus, including two enhancers (Enh1, Enh2), the four promoters (core, S1, S2 and X), polyadenylation, encapsidation (ϵ) and replication signals (DR1, DR2). The four ORFs are those of the Pre-S/S, Pre-core/core, X and polymerase and between them they encode for a total of 7 proteins which are translated from 6 co-terminal mRNAs. These are unspliced and capped, ending at a common polyadenylation signal embedded in the core ORF ([Fig. 3](#)). The synthesis of these mRNAs is regulated by the aforementioned enhancers and promoters which bear motifs which are recognized by transcription factors highly enriched in the nuclei of hepatocytes which are the target cells of the virus.

Transcription and Translation

Surface proteins

The Pre-S/S ORF encodes three proteins which are glycosylated and are part of the viral envelope. These are known as the large (L), middle (M) and small (S) HBsAg, produced by differential initiation of translation at each of three in-frame initiation codons. Of these, the S-HBsAg constitutes the majority protein of the viral envelope. The proteins are translated from two mRNA transcripts of 2.4 kb and 2.1 kb in length, the synthesis of which is under the control of the S1 and S2 promoters respectively. The 2.4 kb transcript is utilized for the synthesis of L-HBsAg whilst the 2.1 kb transcript is responsible for the translation of M- and S-HBsAg, the latter through leaky ribosome scanning. The proteins are co-terminal and the sequence of S-HBsAg consisting of 226 amino-acids is shared by the other two and constitutes their C-terminus. The M-HBsAg has an additional 55 amino-acids at its N-terminus

encoded by the Pre-S2 region, whilst the L protein has 107–118 (depending on genotype) further amino-acids encoded by the Pre-S1 region. A stretch of 75 amino-acids at the N-terminus of Pre-S1 appears to be responsible for the interaction of the virus with its hepatocyte receptor. As mentioned previously, the three proteins are glycosylated, although the L- and S-HBsAg may be present in an unglycosylated form in particles also. In addition to glycosylation the L-HBsAg undergoes one other post-translational modification in the form of myristylation, a step that appears necessary for infectivity and envelopment of the core particles. These proteins are synthesized in close proximity to the ER membrane adopting a transmembrane configuration that facilitates budding of the virus into the lumen during virion maturation.

Core and polymerase

The synthesis of two longer than genome length mRNAs (3.5 kb) which differ with respect to the start of their 5' end is under the control of the core promoter. The precore mRNA is longer by a small number of ribonucleotides amongst which the initiation codon for the synthesis of the precursor of the soluble HBeAg often referred to as the precore protein. This is synthesized when the first of two in frame initiation codons that the precore/core ORF contains is utilized. The N-terminus of this protein has a signal peptide that anchors the protein in the ER membrane. A signal peptidase in the lumen of the ER cleaves the first 19 amino-acids of the protein and what remains undergoes furin cleavage for the removal of an arginine rich domain at its C-terminus. The resulting protein constitutes the 15 kD HBeAg, which is secreted in serum. Initiation of translation at the second initiation codon results in the synthesis of the nucleocapsid or core protein (21 kD). The core has the capacity to dimerize and form nucleocapsids consisting of 240 copies (120 dimers) of the protein through self-assembly. The HBeAg and core proteins are translated from two separate transcripts known as the precore mRNA and the pregenomic RNA (pgRNA), respectively.

The pgRNA is bicistronic in nature as it contains in addition the ORF encoding the polymerase (Fig. 3), a 90 kD protein that encompasses almost $\frac{3}{4}$ of the genome. The polymerase has multifunctional enzymic activities that include a reverse transcriptase (rt), DNA polymerase and RNase H activity. In addition, the pgRNA constitutes the template for synthesis of the (–)-DNA strand by reverse transcription during the replication of the viral genome, as explained later.

X protein

Finally, the fourth ORF encodes for the 17 kD HBx protein that is translated from the shortest transcript of 0.7 kb in length. It consists of 154 amino-acids and has been implicated in a number of actions ranging from modulation of host-cell signal transduction pathways, gene transactivation under experimental conditions, activation of transcription factors and epigenetic control of the covalent closed circular DNA (cccDNA) minichromosome that is essential for transcriptional activation. Moreover, cccDNA can persist in hepatocytes indefinitely thus maintaining chronic lifelong infection until such time as the host cell is eliminated through immune lysis.

Life Cycle

Attachment

Other than the requirement of transcription factors enriched in hepatocytes, it is now evident that species specificity and hepatotropism are determined by the expression of the recently described sodium taurocholate co-transporting peptide (NTCP) on human hepatocytes, which is the HBV receptor (Fig. 4). NTCP is a bile acid transporter expressed at the basolateral membrane of hepatocytes. The receptor-virus interaction is effected by binding of the N-terminal end of L-HBsAg as described above. This may not be the only requirement as evidence suggests co-operative binding in the process of attachment and uptake involving in addition, heparan sulfate proteoglycans and glypican.

Penetration and Uncoating

The virion is likely internalized through clathrin mediated endocytosis. The steps from uncoating to transfer of the nucleocapsid to the nuclear pore are not clear, but it seems that transport factors such as importin alpha and beta and component nucleoporin 153 assist in nucleocapsid delivery to the nuclear basket. The disassembly of the nucleocapsid is followed by the release of the rcDNA genome into the nucleoplasm with its covalently attached polymerase.

Transcription/Translation

Within the nucleoplasm the rcDNA is converted into the cccDNA molecule involving at least three stages. The viral polymerase which is covalently attached to the 5' end of the (–)-DNA strand is removed, as is the short RNA oligomer from the 5' end of the (+)-DNA strand which is used to prime (+)-DNA strand synthesis. Next, the variable (+)-DNA strand is completed and the ends of the two now complete strands ligated to form a double stranded circular molecule, referred to as cccDNA. This is quite stable and functions as a minichromosome following association with a number of epigenetic factors that include histones H3 and H4, transcription factors that include CREB, ATF, STAT1 and STAT2, chromatin modifying enzymes, histone acetyltransferases and deacetylases, as well as the HBc and HBx proteins. Transcriptionally active cccDNA constitutes the template for viral transcript

synthesis by the host RNA polymerase II. Newly synthesized viral transcripts are exported to the cytoplasm for viral protein synthesis.

Encapsidation

As mentioned above the bicistronic pgRNA encoding for the core and polymerase proteins, also serves as the template for DNA synthesis by reverse transcription. The pgRNA is longer than genome length by virtue of a terminal redundancy which duplicates the sequence at its 5' end by about 120 nt and terminates at the polyadenylation signal. The host RNA polymerase appears not to recognize this signal during the first pass but does so on the second encounter. Thus, the redundancy contains a second copy each of the direct repeat 1 (DR1) and the encapsidation signal ε , preceding and incorporating the precore nucleotide sequence respectively.

The encapsidation of the pgRNA into the nucleocapsid involves both viral and host factors. The polymerase has four domains which in sequence are the terminal protein involved in DNA priming, a spacer region of unknown function, the reverse transcriptase/polymerase (rt) and the RNase H which are involved in DNA synthesis and degradation of the pgRNA respectively. The polymerase recognizes and binds to the secondary structure of ε located at the 5' end of the pgRNA, an event that triggers encapsidation of the complex by the core protein (Fig. 5). This process is facilitated by the cap at the 5' end of the pgRNA, as well as eIF4E and heat shock proteins, which in addition support the stabilization and activation of the polymerase. The arginine rich C-terminus of the core protein is involved in pgRNA binding thus facilitating encapsidation also.

The steps that follow are performed within the nucleocapsid. The secondary structure that ε assumes consists of a lower stem, an upper stem, a side bulge and an apical loop, which are the result of base pairing of palindromic nucleotide sequences. Part of the sequence of the side bulge of ε serves as a template for the synthesis of only a 4 nucleotide long DNA primer (Fig. 5(A)). A phosphodiester linkage between dTTP and the hydroxyl group of a tyrosine residue in the terminal protein (position 63), results in the covalent attachment of the primer to this domain of the polymerase. This is followed by a translocation event whereby the polymerase-primer complex localizes to the 3' of the pgRNA, where the primer hybridizes with a homologous region within DR1 (Fig. 5(B)). This is assisted by two other elements, ϕ and ω , which interact with ε . Priming of the pgRNA is followed by the synthesis of the (–)-DNA strand initiated by reverse transcription as the complex proceeds towards the 5' end of the pgRNA, having a terminal redundancy of about 10 nucleotides (Fig. 5(C)). The RNase H activity of the polymerase degrades in the process

Fig. 5 Replication strategy of the virus. (a) Primer synthesis; (b) translocation and binding to DR1; (c) synthesis of the (–)-DNA strand; (d) RNA primer fragment preserved from the degradation of the pgRNA; (e) (+)-DNA strand synthesis. Reproduced from Karayiannis, P., 2017. Hepatitis B virus: Virology, molecular biology, life cycle and intrahepatic spread. *Hepatology International* 11, 500–508, with permission from Elsevier.

the pgRNA except for the final 11–16 or so ribonucleotides which contain the DR1 region at the 5' of the pgRNA (**Fig. 5(D)**). (+)-DNA strand synthesis is primed by the ribonucleotide fragment which hybridizes with DR2 at the 5' end of the newly synthesized (–)-DNA strand with which it shares homology. This event necessitates a second translocation event which is followed by (+)-DNA strand synthesis that proceeds to the 5' end of the (–)-DNA strand. Circularization facilitated by the short terminal redundancy of the (–)-DNA strand allows template exchange and continuation of (+)-DNA strand synthesis along the 3' end of the (–)-DNA strand (**Fig. 5(E)**). The partially double stranded nature of the HBV genome is the result of the depletion of the nucleotide pool which is not replenished once the maturing nucleocapsids are enveloped by budding through the endoplasmic reticulum membrane. The passage of nucleotides is facilitated through pores within the nucleocapsid at the early stages of replication. As a result the (+)-DNA strand remains incomplete.

Maturation

Early in infection and until sufficient amounts of HBsAg accumulate, nucleocapsids containing rcDNA are shuttled back to the nucleus in order to replenish the cccDNA pool. Hepatocyte nuclei may contain more than 50 copies of cccDNA through this amplification loop (**Fig. 4**). In the final stages, virions bud through the endoplasmic reticulum membrane where HBsAg proteins are already localized, into the lumen, acquiring in the process their outer envelope. This is assisted by the topology and conformational arrangement of L-HBsAg. Studies have shown that about half of the protein produced exposes its N-terminus on the cytosolic side of the ER membrane, facilitating binding of the nucleocapsid and initiation of budding. The rest of L-HBsAg has its N-terminus protruding in the lumen which enables exposure on the surface of the virion and thus accessibility for binding to the NTCP receptor.

Egress

Virions that accumulate in the ER lumen rely on the multivesicular body (MVB) pathway for their export. This pathway depends on the endosomal sorting complex required for transport (ESCRT) system which uses ESCRT-0, -I, -II and -III complexes and associated proteins. SVPs on the other hand bud off independently and are processed via the ER-Golgi pathway.

Epidemiology

In spite of the availability of an effective vaccine against HBV and concerted immunization campaigns in endemic areas, there are still about 291 million chronic carriers of HBV infection worldwide, representing 3.9% of the world's population (estimates of 2016). The prevalence of HBV infection has been dropping in many endemic areas, but still this varies by geographical region. In North Western Europe, North America and Australia the prevalence is between 0.1% and 2%, in the Mediterranean region, Eastern Europe, Middle East, Indian subcontinent, Central and South America it ranges between 2% and 7%, whilst in Africa and the Far East it is between 2% and 14%. About two thirds of the world's chronic carriers reside in Africa and the Far East. The geographical distribution of HBV infection is mirrored by the incidence of HCC in the same regions. In areas of high endemicity, the virus is transmitted perinatally from carrier mothers to their infants, or horizontally from infected siblings and other children in early childhood. In areas of intermediate endemicity apart from perinatal transmission, household and sexual contact, as well as percutaneous exposure, are likely routes of infection. Finally in Western countries transmission is nowadays through sexual contact or intravenous drug use. Following infection, the risk of becoming a chronic carrier is age dependent. Exposure to the virus perinatally and up to one year of age has the highest chronicity rate of 90%, an intermediate risk of 20%–50% for ages up to 5, and 5% for older children and adults.

Genotypes

Whole HBV genome nucleotide sequencing of human isolates from various regions of the world, followed by phylogenetic analysis have identified 10 genotypes designated A–J based on sequence divergence of > 8%. These have characteristic geographical distribution such that Genotypes A and D are frequently found in Africa, Europe, and India, genotypes B and C in Asia, genotype E confined to West Africa, and genotype F in Central and South America. Genotypes G and H have been isolated from Central America and Southern Europe but otherwise their distribution is less clear. Two new genotypes designated I and J have recently been described. Genotype I identified in Vietnam, Laos and Eastern India appears to be an intergenotypic recombinant between genotypes A, C, and G, whilst genotype J was isolated in Borneo, and is a recombinant between genotype C and gibbon HBV. Currently, 44 sub-genotypes also exist and are found in Genotypes A, B, C, D, F and I. These are based on nucleotide divergence of 4%; A1–6, B1–9, C1–16, D1–9, F1–4 and I1–2. Of the other recombinants, B/C and C/D types represent the majority, whilst other intergenotypic recombinants that occur less frequently involve most of the other genotypes.

Likely differences between genotypes in relation to pathogenesis and response to antiviral treatment are beginning to emerge. Genotype C is more frequently associated than B with abnormal liver function tests, lower rates of seroconversion to anti-HBe, higher levels of serum HBV-DNA, cirrhosis and hepatocellular carcinoma. Moreover, there is a better sustained response to interferon treatment in patients with genotype B than those with C, and in patients with genotype A than those with D. Genotype A infection appears to be associated with biochemical remission and clearance of HBV DNA more frequently than genotype D, and has a higher rate of HBsAg clearance compared with genotype D. In contrast to the differences observed in response to interferon therapy, treatment with nucleos(t)ide analogs does not show differential responses between genotypes. Recently, quantitative measurements of HBsAg levels have been associated with potentially favorable responses to interferon treatment in both HBeAg-positive and -negative patients. For example, a reduction in HBsAg levels during treatment, particularly at 12 and 24 weeks, may be predictive of a favorable outcome in the case of Peg-IFN treatment in HBeAg positive patients.

Subtypes

The nucleotide sequence encoding HBsAg is shared by all three envelope proteins. What is more, it contains the main virus neutralizing epitope which is referred to as the “a” determinant region. This epitope is hydrophilic in nature and thus displayed on the surface of the virion. It is conformational, assisted in this by a number of disulfide bridges, and thought to encompass amino-acids 110–160 of the protein. It is shared by all virus isolates. Subtypic specificities also exist and these can be defined either by specific antibodies or by the amino-acids present at positions 122 and 160 of the protein. Lysine (K) or arginine (R) at position 122 confers d or y specificity, respectively, whilst specificities w and r are conferred by the presence of K or R at position 160. Thus each subtype is given a 3 letter code e.g., adw, whereby the a is the group determinant, and d and w based on the amino-acids present at positions 122 and 160 respectively. The w sub-determinant is further divided into w1–w4 specificities. Nine subtypes of the virus are recognized in all (Table 1) depending on the presence of other subtypic determining amino-acids elsewhere in the “a” determinant region.

Variants

Other than the above stable genotypes and subgenotypes, a number of genomic mutations have been described which arise during the natural history of the infection. As described above, the replication step in the HBV life cycle that entails the reverse transcription of the pgRNA replicative intermediate to synthesize the (–)-strand DNA of the virus is prone to errors by the viral

Table 1 Genotype determining amino acid variation over the “a” determinant region of HBsAg, and relationship between genotypes and subtypes.

[illegible]

Source: a = R or K.

Note: G and I share complete amino-acid homology over the "a" determinant. Distinction between the two is possible as R in genotype G is substituted by K at position 24 of S-HBsAg in genotype I. The latter is also distinguished by the presence of H, A, N, V and V at positions 56, 60, 87, 90 and 91 of L-HBsAg respectively and I at position 22 of M-HBsAg.

reverse transcriptase. It is estimated that the HBV genome evolves at a rate of $1.4\text{--}3.2 \times 10^{-5}$ nucleotide substitutions/site/year. As a result, the virus circulates in the serum of infected patients as a population of very closely related genetic variants, referred to as quasispecies. The viability of these variants is dependent on the site of the nucleotide substitutions given the overlapping nature of the ORFs and the localization of the various regulatory elements. Therefore some of these mutations may be deleterious to the virus whilst others may be advantageous, offering either a replication advantage or facilitating immune escape. These are discussed later in the clinical settings in which they have been described.

Clinical Features

HBV Infection may run an asymptomatic, acute icteric (jaundice) or in a minority of patients a fulminant hepatitis course (0.1%–0.5%). As already mentioned the risk of the infection progressing to chronicity is inversely related to age with approximately 5% of adults and 95% of young children becoming chronically infected. Other than age, outcome depends on genetic factors which likely influence the efficiency of the host immune response. These include polymorphisms of the MHC class II glycoproteins involved in viral peptide presentation during induction of the cellular immune response and mannin binding lectins which bind to mannose terminated carbohydrate residues, such as those present on the carboxy-terminus of the pre-S2 region of the middle envelope protein, facilitating phagocytosis.

Acute HBV Infection

The incubation period following exposure is variable ranging from 3 to 6 months and may be dependent on the size of the inoculum and route of exposure. Before onset of symptoms some patients may experience a serum sickness-like syndrome including arthralgia, fever and urticaria. The clinical picture varies from asymptomatic anicteric infection to protracted icterus and, in some patients (< 1%), liver failure (fulminant hepatitis). The acute infection is self-limiting and most patients recover within 1–2 months after the onset of icterus.

Chronic HBV Infection

This is defined as persistence of HBs antigenaemia of longer than 6 months duration and may or may not be accompanied by viraemia and hepatic inflammation. The latter is based on histological examination of liver biopsy material that is followed by assignment of a score for necro-inflammatory activity (out of 18) and stage of fibrosis (out of 6) which are used to assess disease progression and to determine whether a patient needs therapy.

Course of Chronic Infection

Chronic HBV infection is quite variable and is typically characterized by four main phases. These have recently been renamed as the “HBeAg-positive chronic HBV infection” (previously immune tolerant), the “HBeAg-positive chronic hepatitis B” (immune clearance), the “HBeAg-negative chronic HBV infection” (non-replicative), and the “HBeAg-negative chronic hepatitis B” (reactivation phase) which may be seen in some patients, particularly in Southern Europe and the far East (**Fig. 6**). There may be a fifth phase in some patients, referred to as the “HBsAg-negative phase”, which is characterized by absence of serum HBsAg and positivity for anti-HBc with or without detectable anti-HBs. This phase is also known as “occult HBV infection”. During the HBeAg-positive chronic HBV infection phase the patient is HBeAg positive with high levels of HBV-DNA, but with near normal or minimally elevated alanine aminotransferase (ALT) levels and absent or minimal necroinflammation changes in the liver. This phase is more likely in children infected at birth or soon after, and may last 2–3 decades. Patients are highly infectious and HBeAg loss during this phase is very low indeed. Patients from this phase progress to the HBeAg-positive chronic hepatitis B phase which is more commonly seen in those infected in adult life. This phase is characterized by the presence of HBeAg and HBV-DNA the levels of which gradually decline, as well as increased ALT levels associated with necroinflammatory changes in the liver. Loss of HBeAg may be accompanied by an ALT flare, culminating in loss of HBeAg and seroconversion to anti-HBe in a large proportion of patients followed by entry to the HBeAg-negative chronic HBV infection. During this phase plasma HBV-DNA may remain undetectable, ALT levels return to normal whilst annual loss of HBsAg and/or seroconversion may occur spontaneously in 1%–3% of cases. A few patients from this phase and the rest from the previous may proceed to the HBeAg-negative chronic hepatitis B. These patients have raised ALT levels that may fluctuate from time to time, viraemia and continued necroinflammatory activity in the liver that may lead to fibrosis, and faster development of cirrhosis and HCC. Viral DNA integration into the host genome may take place early on in infection and HBsAg expressed from such sequences contributes to the total throughout chronic infection. Moreover, HBV DNA integration may contribute to the development of cancer in the long term. Finally, patients in the fifth HBsAg-negative phase have normal ALT values and usually, but not always, undetectable serum HBV DNA. cccDNA quiescent in the liver may cause viral reactivation following immunosuppression as may be the case for organ transplantation.

Fig. 6 Diagram of the natural history of HBV infection showing progression from acute to the newly renamed chronic phases of infection. Loss of HBsAg at any time during chronic infection as indicated, may lead to the establishment of occult B infection (OBI).

Mutant Viruses and Chronic Infection

Patients in the HBeAg-negative chronic hepatitis B carry natural mutants of the virus which impact HBeAg production by either reducing levels (core promoter variants) or abrogating completely HBeAg (pre-core variants) production. These variants are selected at the time of, or soon after seroconversion, and become dominant during the reactivation phase. The most common precore mutation is the G1896A substitution, which creates a premature stop codon in the precursor protein from which HBeAg is elaborated. This mutation is located in the stem of the ε encapsidation signal, which it does not destabilize but affords stronger base-pairing with the A1896 change in genotypes with a T at position 1858 of the precore region, such as B, C, D and E. A double mutation in the basal core promoter region (A1762T, G1764A) is suggested to result in decreased transcription of the precore mRNA, with a knock on effect on HBeAg production, whilst pgRNA synthesis remains unaffected. Additional mutations in this region may also contribute to this phenotype.

Pathogenesis

The outcome of infection following exposure to HBV is variable with regards to probability of progression to chronic infection, the likelihood of a favorable outcome after antiviral treatment and the risk of progression to unwelcome chronic sequelae such as cirrhosis and HCC. All of these are dependent on viral, environmental, demographic and clinical factors, but also host genetics and other factors which have been identified such as defective viral mutants (pre-S/S deletion mutants), and more recently spliced mRNAs, miRNAs and exosomal vesicles.

Acute self-limiting infection is characterized by necroinflammation in the liver, consistent with the rise in transaminase levels. It seems that the innate immune response in the initial stages of infection is not robust enough while viraemia decline prior to symptom appearance may indicate non-cytolytic suppression of virus replication, mediated perhaps by $\text{IFN}\gamma$ secreted by NK and NKT cells. Studies in animal models have indicated that an HBV-specific cytotoxic T cell response (CTL) is essential for clearance of infected hepatocytes. Such CTL responses are strong and polyclonal in nature, directed against viral proteins such as HBeAg, and are the prime cause of immunopathology in the liver as the virus is not directly cytopathic. Clearance of free virions and prevention of attachment are dependent on the development of neutralizing anti-HBs.

In chronic HBV infection on the other hand, the virus and high levels of HBsAg or HBeAg may disrupt maturation of antigen presenting cells such as dendritic cells (DCs), thus inducing tolerance. Studies have shown that NK cells and plasmacytoid DCs

(pDCs) are deficient or dysfunctional. Monocytes/macrophages, NK, NKT and T cells (including regulatory T cells) infiltrate the liver and cause chronic inflammation, as a result of induction of pro-inflammatory cytokines, resulting in immunopathology. CTL responses are narrow and monospecific and not sufficient to clear infected hepatocytes. Such cells are deficient in proliferation and production of cytokines such as IFN γ . Intrahepatic CD8 $^{+}$ T cells express programmed cell death protein 1 (PD-1) which suggests that they may become exhausted in the presence of cognate antigen expression.

Long term infection with HBV associated with active viral replication can lead to cirrhosis and HCC. HBV is responsible for 30% of cases with cirrhosis and almost 50% of cases with HCC. The annual risk of HCC in patients with cirrhosis has been reported to be 2%–5%. Recurrent liver necro-inflammation due to the immunopathological events described above, accelerate hepatocyte turnover and deposition of collagen initially but gradually leading to fibrosis, cirrhosis and eventually HCC. This is a long term process, multifactorial in nature and implicating both host and viral factors. These include high HBV DNA levels (>2000 IU/ml), high transaminase levels, prolonged HBeAg positivity, genotypes B, D and F, precore and basal core promoter variants, male sex and older age. Co-infections with HIV and hepatitis D virus, comorbid conditions such as diabetes mellitus and obesity, abuse of alcohol, carcinogen exposure such as smoking and aflatoxin B1, are also contributing factors. Integration of the viral genome into hepatocyte DNA can lead to chromosomal instability and expression of functional preS/S and X proteins which are truncated at their extreme carboxyl end. PreS/S proteins with deletions and mutations in HBx have been associated with increased risk of HCC. HBx is thought to promote viral replication and is a known transactivator *in vitro*, it inhibits TNF- α , Fas-induced apoptosis, whilst it promotes fibrogenesis and remodeling of extracellular matrix. In addition, spliced HBV mRNAs have been implicated in tumorigenesis as have microRNAs (miRNAs) which are involved in regulating gene expression, cell cycle progression, differentiation and apoptosis. Finally, exosomal vesicles are involved in virion export, cell-to-cell spread of the virus, miRNA export etc., which may be additional contributors to viral pathogenesis.

Diagnosis

Acute or chronic infection with HBV is based on serological detection of HBsAg in serum. Its persistence longer than 6 months indicates progression to chronic infection, whilst appearance of anti-HBs (antibody to HBsAg) indicates recovery from infection, or acquired immunity after prophylactic vaccination. Detection of HBeAg indicates active viral replication, as does the detection of serum HBV-DNA by qualitative or quantitative polymerase chain reaction (PCR) tests. The latter is particularly useful in monitoring efficacy of antiviral treatment. Seroconversion to anti-HBe occurs after recovery from acute infection, and less often during the chronic phase, either spontaneously or after therapeutic intervention. In the latter case, this leads to a quiescent phase of disease that can be long-term, but does not necessarily mean that virus replication has stopped entirely (see below). Antibody to core antigen (anti-HBc) of IgM class at high level is a marker of acute infection, whereas total anti-HBc (primarily IgG) is detectable following acute and throughout chronic infection.

Treatment

Antiviral treatment is the only means available to prevent progression of chronic infection to cirrhosis and eventually HCC. The primary aim is the long term suppression of viral replication to undetectable levels. Moreover, in HBeAg positive patients the loss of this marker and preferably the development of the respective antibody (anti-HBe) is a favorable outcome as it denotes immune control of the virus. These responses are accompanied by normalization of biochemical markers. A secondary outcome which is achieved less often is the loss of HBsAg with or without development of anti-HBs. Decision to treat is based on a viral load >2000 IU/ml, an ALT level above the ULN and the presence of moderate necroinflammation and fibrosis. Patients with HBV DNA levels >20000 and ALT levels more than 2xULN should be treated without histological assessment. Two approaches are currently available for antiviral treatment of chronic HBV infection; nucleos(t)ide analogs (NAs) and immunomodulators, such as Pegylated Interferon α (PegIFN α).

NAs are lamivudine (LAM), adefovir dipivoxil (ADV), entecavir (ETV), telbivudine (TBV), tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). Of these ETV, TDF and TAF are the drugs of choice as they have a very high barrier to HBV resistance as opposed to the other three which have a low resistance barrier. NAs are taken orally and act as chain terminators at the stage of DNA synthesis. They are chemically modified so that their incorporation into nucleic acids prevents chain elongation and therefore cause premature termination of synthesis. These lend themselves for long-term treatment which effectively leads to suppression of HBV DNA to undetectable levels very quickly which is maintained whilst the patient remains on treatment. They are quite safe and can be used in any HBV infected patient whether HBeAg-positive or -negative, but also various subgroups including those with decompensated cirrhosis, liver transplant patients, acutely infected or those with severe flares during chronic HBV. NAs can also be used in patients with occult HBV to prevent reactivation if they are due to be immunosuppressed.

5 years of ETV or TDF treatment in HBeAg-positive patients results in nearly 99% and 97% cumulative virologic response and near 53% and 49% HBeAg loss respectively. HBsAg loss was achieved in 10% and HBsAg seroconversion in 8%. For HBeAg-negative patients, treatment with ETV and TDF over the same period achieved virological and biochemical responses of 98% and 95% and 99% and 88%, respectively. Very few such patients (1%) achieved HBsAg loss during treatment exceeding 5 years duration. Data on TAF treatment is available for the first two years since its licensing with comparable results to TDF. In HBeAg-

positive patients, the rates of virologic response at week 96 was 75%, whilst HBeAg loss and anti-HBe seroconversion were achieved in 22% and 18%, respectively. Only 1% of patients cleared HBsAg. In HBeAg-negative patients, TAF achieved a virologic response in 90% of them by week 96.

PegIFN α acts by promoting cytotoxic T-cell activity for lysis of infected hepatocytes and by stimulating cytokine production for control of viral replication. Weekly intramuscular injections in HBeAg-positive patients for 1 year can lead to seroconversion to anti-HBe in 32% of patients. This is sustainable in over 95% of patients. In HBeAg-negative patients the intention is to suppress HBV- DNA levels followed by ALT normalization a goal which is achievable in about 44% of them. However, durability is only possible in around 20%. To manage such relapses following initial interferon treatment, nucleos(t)ide therapy should be started and continued long term in both HBeAg positive and negative patients not achieving a sustained response on PegIFN. Rates of HBsAg loss following 12 months of treatment are 3%–7%. Overall, among sustained responders whether HBeAg-positive or -negative 30% will clear HBsAg in the long-term.

Resistance

Treatment with NAs of low genetic barrier to resistance over time can lead to increasing resistance levels. In the case of LAM for example, this is about 24% at year 1 rising to >70% by year 5. Adefovir resistance on the other hand is delayed being 0% at year 1, 3% at year 2 and rising to 29% by year 4. Entecavir resistance has only been seen so far in patients with lamivudine resistant strains. Resistance is associated with the acquisition of amino-acid substitutions in the rt domain of the HBV polymerase which has 6 spatially separated subdomains from A-F and which contribute to nucleic acid synthesis. Most importantly, amino-acid substitutions in subdomain C which contains the characteristic YMDD (tyrosine-methionine-aspartate-aspartate) motif of the catalytic site of the enzyme can cause resistance. Resistance to LAM relates to substitution of the methionine (M) at position 204 to either valine (YVDD, rtM204V) or isoleucine (YIDD, rtM204I). The rtM204V substitution mutation is almost always associated with a second one involving a substitution of leucine with methionine at position 180 (rtL180M) in subdomain B. ADV resistance is conferred by mutations rtN236T in subdomain D and rtA181V in subdomain B, whilst the small number of entecavir resistant cases have in addition to the lamivudine resistant substitutions additional ones such as rtI169T, rtT184G, rtS202I and rtM250V.

Prevention

Protection against HBV infection is afforded by prophylactic vaccination which was first introduced in the early 1980s. Current vaccines consist of recombinantly expressed HBsAg in yeast such as *Saccharomyces cerevisiae*. In adults, the vaccine is administered through intramuscular injection in the deltoid in a three dose schedule at 0, 1 and 6 months. In countries of high and medium sero-prevalence, universal vaccination programs have been instituted, and HBV vaccination is recommended for infants born to carrier mothers preferably within the first 12 h of life, given together with hepatitis B immune globulin (HBIG). Measuring anti-HBs levels 1–4 months after the last dose of the vaccine ensures development of protective immunity defined as a level >10 mIU/ml.

Response rates to the vaccine in healthy individuals range from 90% to 95%, whilst in haemodialysed and hemophiliac patients these are lower (70%). The durability of the response to the vaccine with persistence of anti-HBs levels >10 mIU/ml has extended beyond 12 years in up to 80% of individuals immunized at a young age. Booster immunizations therefore may not be necessary for at least 10 years after vaccination. However, high risk professions such as healthcare personnel and individuals in high risk groups need to monitor antibody levels perhaps every 5 years.

The impact of HBV vaccination on infection prevalence has become apparent from epidemiological studies around the world and in countries of medium to high endemicity. They have recorded a dramatic drop in HBV prevalence. For example, in Taiwan, 15 years after the start of the vaccination program, the prevalence of HBsAg in children under 15 years of age had decreased from 9.8% in 1984 to 0.9% in 1999 and by 2014 to 0.3%. Similarly, the incidence of HCC has been on the decline from 0.7 per 10,000 children between 1981–1986, to 0.57 and 0.36 between 1986–1990 and 1990–1994, respectively.

In spite of vaccination, breakthrough infections in vaccinated subjects have been detected through monitoring in spite of the presence of a satisfactory antibody levels. Such infections may be due to the wild type virus or mutant viruses, the commonest of which involves a G145R substitution in the “a” determinant region of HBsAg. This and a number of other mutations in this region, which can occur in combination also, alter the antigenic structure of this epitope, causing failure in its recognition by neutralizing antibody. Mutant viruses have also been described in the setting of liver transplantation where use of HBIG or monoclonal anti-HBs is recommended in an attempt to prevent infection of the new liver graft.

Hepatitis C Virus (*Flaviviridae*)

Ralf Bartenschlager and Keisuke Tabata, Heidelberg University, Heidelberg, Germany

© 2021 Elsevier Ltd. All rights reserved.

This is an update of R. Bartenschlager, S. Bühler, Hepatitis C Virus, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00416-7](https://doi.org/10.1016/B978-012374410-4.00416-7).

Glossary

Chronic hepatitis C A liver disease with continued presence of HCV RNA in the blood for six months or more after primary infection.

DAAs Direct acting antivirals, i.e., drugs targeting distinct viral proteins and inhibiting their function, thus disrupting virus replication.

HCV viremia Presence of HCV RNA in the blood of an infected individual.

Internal ribosome entry site (IRES) A folded RNA element that allows for cap-independent initiation of RNA translation. The specific type of IRES determines which subset of the canonical translation initiation factors is required for RNA translation.

Polyprotein A precursor polypeptide from which distinct proteins are produced by proteolytic cleavage.

Positive-strand RNA virus A virus with a single-strand RNA genome that has the polarity of a cellular mRNA and therefore, can be used by host cell ribosomes for RNA translation to produce viral proteins. For that reason, the positive-strand RNA genome is infectious, i.e., it is sufficient to produce virus progeny in a permissive host cell.

Replicon A DNA or RNA molecule capable of self-replication in a cell or an adequate in vitro system (e.g., cell lysate).

Sustained virological response (SVR) Continuous absence of virus from the serum, starting at a given time point after cessation of antiviral therapy. For instance, in HCV infection SVR6 means absence of HCV RNA 6 months after termination of therapy.

Classification

HCV has been classified as a member of the genus *Hepacivirus* and is grouped together with the genera *Pestivirus*, *Pegivirus*, and *Flavivirus* in the family *Flaviviridae*. Based on genomic heterogeneity, 8 genotypes having more than 30% nucleotide sequence divergence and more than 80 subtypes differing from each other by 10%–30% at the nucleotide sequence level have been defined. Subtypes are designated by lower case letters following the number of the genotype (e.g., genotype 1 subtype b = 1b). Genotype 1 is the most prevalent worldwide (~45% of all HCV cases), followed by genotype 3 (~30% of all HCV cases). Genotypes 2, 4, and 6 are responsible for ~23% of all HCV infections, whereas infections with genotypes 5 constitute ~1% of all HCV cases worldwide. Currently, there is no information available about the global prevalence of genotype 7.

Infections with genotype 1–3 are found in almost all countries, whereas HCV genotypes 4–7 are to a large extent restricted to distinct geographical regions like Africa and Middle East (genotype 4), South Africa (genotype 5), and Southeast Asia (genotype 6). Genotype 7 has been isolated in Canada and Belgium from patients possibly infected in Central Africa. A novel genotype 8 was recently identified in 4 patients that migrated from Punjab State, India to Canada. Individual genotypes have not been ascribed to particular disease manifestations except for a higher prevalence of hepatosteatosis for patients infected with genotype 3 viruses. However, in the case of interferon (IFN)-based therapy, the infecting genotype is an important predictor of therapy outcome, although with the implementation of IFN-free antiviral drugs, the genotype has become much less relevant (see below).

Virion Structure and Properties

HCV particles are enveloped and spherical with a very pleomorphic structure. They are most likely composed of a single copy of the viral RNA genome that associates with multiple copies of the core protein (Fig. 1). It is unclear whether a regular nucleocapsid is formed or a more unstructured ribonucleoprotein complex. Surrounding the capsid is a lipid envelope, probably derived from the endoplasmic reticulum (ER). Into this envelope, multiple copies of a heterodimeric complex of the two envelope glycoproteins E1 and E2 are embedded. A hallmark of HCV particles is their association with various apolipoproteins of the host cell, most notably apolipoprotein E (ApoE). This association occurs within the cell, perhaps during assembly or virion egress, but also outside of the cell with released virus particles binding to apolipoprotein-containing very low-density lipoproteins (VLDL), LDL and high-density lipoproteins (HDL). This association is mediated most likely by the viral envelope glycoproteins binding to various apolipoproteins. Because of this tight association, infectious HCV particles have an irregular structure, a very low density and therefore, they have been designated as lipoviro-particles (Fig. 1). Moreover, HCV particles have a unique lipid composition containing an unusually high amount of cholesterol esters and a surprisingly low amount of phosphatidylethanolamine, thus resembling the composition of (V)LDL, but being very different from the lipid composition of e.g., HIV-1 particles. Because of the

Fig. 1 *Morphology and composition of HCV particles.* (A) Schematic presentation of the HCV particle structure and composition. (B) Electron micrograph of negatively stained HCV particles. Virions were produced in cell culture and captured using electron microscopy grids coated via protein A with anti-HCV antibodies. Scale bar: 20 nm. (C) Cryo-electron microscopy image of an HCV particle at 78,000 $\times$ magnification. Virions are heterogeneous in size ranging from 45 to 86 nm in diameter, with a mean diameter of 68 nm. The illustration is adapted from Bartenschlager, R., Penin, F., Lohmann, V., André, P., 2011. Assembly of infectious hepatitis C virus particles. *Trends in Microbiology* 19, 95–103. Copyright 2010, Elsevier Ltd. Images are reproduced from Catanese, M.T., Uryu, K., Kopp, M., *et al.*, 2013. Ultrastructural analysis of hepatitis C virus particles. *Proceedings of the National Academy of Sciences of the United States of America* 110, 9505–9510. with permission of the authors.

association of HCV particles with apolipoproteins and (V)LDL and HDL components, size, density and composition of the virions differ, depending on the culture conditions. HCV produced in the human hepatoma cell line Huh7, which supports robust virus replication, have a density of 1.1 g/mL whereas virions produced in more authentic cell systems such as Huh7 cells cultured in human serum or primary human hepatocytes can have a much lower density (close to 1.0 g/mL). The association with lipoprotein components reduces sensitivity of the virus to neutralization by antibodies and increases virion infectivity.

Genome Organization and Viral Proteins

The genome of HCV is a single-stranded RNA molecule of positive polarity and has a length of ~ 9600 nucleotides (**Fig. 2(A)**). It is flanked by two highly structured non-translated regions (NTRs). The about 340 nucleotides long 5' NTR contains an internal ribosome entry site (IRES) (**Fig. 2(B)**), mediating cap-independent RNA translation giving rise to an around 3,000 amino acids long polyprotein. The 3' NTR is composed of an about 40 nucleotides long variable region, a polypyrimidine tract (heterogeneous in length) and a 98 nucleotides long highly conserved 3' terminal X-tail (**Fig. 2(B)**). Both the 5' NTR and the 3' NTR contain cis-acting RNA elements (CREs) that are required for viral replication. Within the 3' terminal part of the NS5B gene 3 additional CREs are localized (5BSL3.1 to 5BSL3.3) with 5BSL3.2 being absolutely required for viral RNA replication by forming a long-distance RNA-RNA interaction with the middle stem-loop in the X-tail. Likewise, 4 CREs have been identified in the core protein coding region with two of them (SL47 and SL87) contributing to HCV RNA translation and robust replication in cell culture. The importance of the structural integrity of SL87 for robust HCV replication was confirmed *in vivo* using mice xenografted with primary human hepatocytes and in chimpanzees.

Flanked by the two NTRs is the coding region of the HCV polyprotein that is cleaved proteolytically into 10 products (**Fig. 2(A)**). The structural proteins core, E1 and E2 are located within the N-terminal part of the polyprotein preceding the p7 protein, which appears to be an ion channel and therefore, was grouped into the viroporin protein family. The non-structural (NS) proteins NS2, NS3, NS4A, NS4B, NS5A, and NS5B are encoded in the remaining part of the polyprotein. The NS2 protein, together with the N-terminal protease domain of NS3, is responsible for the autocatalytic cleavage of the NS2-NS3 junction (**Fig. 2(A)**). NS2 is a dimeric cysteine

Fig. 2 HCV genome organization, gene products and *cis*-acting RNA elements (CREs). (A) The HCV polyprotein coding region is flanked by two non-translated regions (5' and 3' NTR) represented in dark gray. The 5' NTR contains an internal ribosome entry site (IRES). Polyprotein cleavage by cellular signal peptidases is indicated by scissors, whereas cleavage by the viral NS3 serine protease is indicated by solid arrows. The cleavage at the NS2-NS3 junction by the NS2 cysteine protease is indicated by a dotted arrow. The star indicates the cleavage site for the cellular signal peptide peptidase removing the carboxy-terminal region of the core protein. Functions of the individual cleavage products are specified in the figure. (B) Schematic representation of CREs. The 5' NTR (left panel) contains the IRES as well as structures important for viral RNA replication. The middle left panel depicts the four CREs in the core coding region. Three CREs are located in the 3'-terminal part of the NS5B coding region (middle right panel). Stem-loop 5BSL3.2 forms a long-distance RNA-RNA interaction essential for RNA replication with the loop of the middle stem-loop in the X-tail. The right panel displays the organization of the 3' NTR with the variable region (v.r.), the poly U/UC-tract and the X-tail. Positions of start and stop codons are indicated with dots.

protease with a composite active site. The N-terminal NS3 domain carries a serine-type protease that after association with its cofactor NS4A, cleaves the four junctions between NS3 and NS5B. Two additional enzymatic activities (RNA helicase and nucleoside triphosphatase) reside in the carboxy-terminal two thirds of NS3.

Structural integrity of intracellular membranes is altered by NS4B that has a complex and dynamic membrane topology. NS4B cooperates with NS5A, which is a zinc-binding phosphoprotein, composed of the following domains (from the N- to the C-terminus): an amphipathic α -helix serving as a peripheral membrane anchor, the structured domain I, low complexity sequence I, domain II, low complexity sequence II and domain III. Interestingly, domains II and III are intrinsically unfolded, but they also contain segments of transient secondary structure. The X-ray crystal structure of domain I was resolved and found to form various types of homodimers with one of them forming a basic RNA binding groove. NS5A is phosphorylated by several cellular kinases including the casein kinase I isoform alpha (CK1 α), CKII, polo-like kinase 1 (PLK1) and calmodulin-dependent kinase II gamma (CaMKII γ) and CaMKII δ . The phosphorylation state of NS5A affects its interaction with several host cell proteins such as VAP-A/B, arguing that distinct phosphorylation patterns confer different functions to NS5A, depending on an associating partner molecule. In this respect, NS5A exerts multiple functions; it is essential for viral RNA replication and virion assembly, but it is also involved in counteracting antiviral defenses such as the IFN response. The exact mechanism by which NS5A contributes to RNA replication has not been revealed, but it was found that the sole expression of NS5A can induce the formation of double membrane vesicles (DMVs), which are the presumed sites of HCV RNA replication (Fig. 3, inset). Moreover, drugs targeting NS5A block DMV formation, suggesting that the induction of the HCV replication organelle, designated "membranous web", is one way by which NS5A contributes to HCV RNA replication. In addition, NS5A interacts with the core protein, for which phosphorylation of the carboxy-terminal region of NS5A is required. Thus, phosphorylation of NS5A at this site appears to trigger the assembly of infectious HCV particles, a process that may be supported by the interaction between RNA-loaded NS5A and the core protein.

The 68-kDa protein NS5B is an RNA-dependent RNA polymerase (RdRp). It is a tail-anchored membrane protein with a structural organization similar to that of other polymerases, i.e., composed of palm, finger and thumb subdomains. However,

Fig. 3 *HCV replication cycle.* (Attachment) HCV binds to one or several receptors on the surface of the host cell. HSPG, SRB1, CD81 and presumably LDLR are required for or contribute to virus binding and entry. (Internalization) The virus particle enters the cell via clathrin-mediated endocytosis likely at tight junctions where Claudin-1 (CLDN1) and occludin (OCLN) reside. (Fusion) After a low-pH mediated fusion step from within an acidic endosome and uncoating, the HCV genome is released into the cytoplasm of the host cell. (RNA translation and replication) The viral RNA genome (red line) is translated at the rER and a membranous web, presumably originating from ER membranes in close proximity to lipid droplets (LD), is formed (DMV formation). DMV is the site of viral RNA amplification, which occurs via negative-strand RNA intermediates (blue line). Newly synthesized positive-strand RNA is used either for translation, or for replication, or the RNA is packaged into nascent capsids (Assembly). This most likely occurs at the ER where E proteins are retained with virus particles forming via budding into the ER lumen. (Maturation) During or after envelopment virus particles acquire ApoE, which is thought to be required for virion infectivity (indicated with the question mark). The association of HCV particles with ApoE and other apolipoproteins, occurs intra- and extracellularly. (Secretion) Virions are release after fusion of the transport vesicle with the plasma membrane. A three-dimensional reconstruction of the membranous web in HCV-infected cells is shown on the bottom left. The inner DMV membrane is indicated in light brown whereas ER is depicted in dark brown. Single-membrane vesicles, cytoskeletal filaments and Golgi cisternae are shown in violet, blue and green, respectively. Scale bar: 100 nm. The illustration is adapted from Neufeldt, C.J., Cortese, M., Acosta, E.G., Bartenschlager, R., 2018. Rewiring cellular networks by members of the Flaviviridae family. *Nature Reviews Microbiology* 16, 125–142. The inset image is reproduced from Romero-Brey, I., Merz, A., Chiramel, A., *et al.*, 2012. Three-dimensional architecture and biogenesis of membrane structures associated with hepatitis C virus replication. *PLOS Pathogens* 8, e1003056.

NS5B differs from most other RdRps by having a fully encircled active site, which is due to tight interactions between the finger and the thumb subdomain.

Apart from the polyprotein a heterogeneous group of HCV proteins are expressed either by ribosomal frameshifting into the + 1 ORF or by internal translation initiation. The resulting proteins, collectively designated core + 1 (Fig. 2(A)), are not essential for replication and virus production in cell culture and they appear to be dispensable *in vivo*.

Life Cycle

Hepatocytes are the primary target cells for HCV. However, viral RNA was also detected in PBMCs and bone marrow cells, but it is unclear whether a productive infection is possible in these cell types. In cell culture, HCV RNA replication was demonstrated in non-liver

cells like human T and B cell lines, human embryonic kidney cells (HEK293) and even neuroepithelioma-derived cell lines arguing that some of the extrahepatic manifestations observed with chronic hepatitis C patients, such as cryoglobulinemia or central nervous system abnormalities, might be caused by infection of these cell types. Furthermore, certain mouse cell lines can support the replication of engineered HCV replicons demonstrating that the viral replication machinery is also functional in a murine host cell environment.

In hepatocytes, HCV infection starts with virion binding to host cell attachment factors such as heparan sulfate proteoglycans (HSPG) and low-density lipoprotein receptors (LDLR) located at the basolateral membrane (Fig. 3). Subsequently virus particles interact with the scavenger receptor class B member 1 (SRB1) and the tetraspanin CD81, which guide the lateral translocation of virion - receptor complexes towards tight junctions upon activation of the epidermal growth factor receptor (EGFR) and the EGFR/Shc/Grb2/Hras signaling pathway. Following these events, CD81 associates with claudin-1 (CLDN1) and occludin (OCLN) to trigger virus internalization through the clathrin-dependent pathway and a subsequent fusion step from within an acidic endosomal compartment (Fig. 3).

Upon release of the RNA genome into the cytoplasm, the polyprotein is synthesized by IRES-dependent RNA translation occurring at the rough ER (rER) where host cell signal peptidases, signal peptide peptidases and viral proteases catalyze polyprotein cleavage. During or after polyprotein cleavage an ER-derived membranous web is formed where the positive-strand RNA genome is amplified via a negative-strand RNA intermediate (Fig. 3). Newly synthesized positive-strand RNAs are used for the synthesis of multiple polyprotein copies (probably > 1000 protein copies per RNA molecule), or they serve as templates for further RNA synthesis, or they are incorporated into assembling virions. Viral envelope (E1-E2) glycoproteins are retained at rER membranes suggesting that viral envelopes are generated by budding into the lumen of this organelle. The envelopment of virus particles depends on components of the ESCRT (Endosomal Sorting Complex Required for Transport) machinery. The ESCRT-0 complex component HRS (hepatocyte growth factor-regulated tyrosine kinase substrate) interacts with HCV NS5A and NS2 proteins, at least in case of the latter via recognition of polyubiquitinated residues. Other ESCRT proteins may interact with HRS to coordinate HCV assembly, as the depletion of the components of ESCRT-III or VPS4-VTA1 complexes causes assembly defects. Given the strong functional relationship between HCV and lipoproteins, it was speculated that HCV particles exit the cell via the canonical secretory pathway, comparable to VLDL. However, recent evidence suggests that HCV may also use an alternative secretion route bypassing the Golgi apparatus. In either case, virus particles are released after fusion of the transport vesicle with the plasma membrane as cell-free virions, or they are transmitted directly to neighboring cells via a cell-to-cell spread mechanism.

Formation of the HCV Replication Organelle

The most abundant components of the membranous web are double membrane vesicles (DMVs) that have an average diameter of about 200 nm (Fig. 3, inset). Although the sole expression of NS5A suffices to induce DMVs, the efficiency of DMV formation is greatly increased upon the expression of an NS3-5B polyprotein. Morphologically, DMVs correspond to protrusions from the ER membrane with a fraction of DMVs being connected via the outer DMV membrane to the ER membrane. DMVs isolated from HCV-replicating cells contain active viral replicase arguing that DMVs are the site where HCV amplifies its genome. However, only a minority of DMVs has an opening connecting the DMV lumen with the cytoplasm, whereas the majority of DMVs appears to be completely "sealed". Thus, viral RNA produced inside DMVs can either be released into the cytoplasm as long as the DMVs are not completely sealed or DMVs contain specific "pores" spanning both membranes and allowing RNA export out of the DMV interior. Interestingly, similar DMV-type viral replication organelles have been described for other positive-strand RNA viruses, including members of the distantly related *Coronaviridae*, *Arteriviridae*, and *Picornaviridae* families.

At least in the case of HCV, the formation of DMVs may be linked to autophagy as deduced from the impaired RNA replication and reduced DMV number upon depletion of distinct factors of the autophagy machinery. Given the structural similarity of autophagosomes and DMVs, a link to autophagy appears plausible. However, in the case of poliovirus, it was shown that DMVs form via "secondary" invagination of single membrane vesicles, which appear to be the primary membrane structures induced by poliovirus early after infection. In contrast, single membrane vesicles have been observed only rarely in HCV-infected Huh7 cells, but they have been reported as sole structures in hepatocytes of HCV-infected individuals. Thus, it remains to be determined whether DMVs are *bona fide* HCV replication sites formed only in hepatoma cell lines or whether they are also found in vivo.

Although HCV-induced DMVs are derived from the ER membrane, their lipid composition differs substantially from the originating membrane by having much higher levels of cholesterol and sphingolipids. This change in lipid composition is achieved by the NS5A-mediated recruitment and activation of the lipid kinase phosphatidylinositol 4-kinase III α (PI4KA) that is enriched at (NS5A-containing) membranes to produce excessive amounts of PI4P. In addition, NS5A binds to and recruits, probably via VAP-A/B, lipid-transfer proteins such as oxysterol-binding protein that may deliver cholesterol into the DMV membrane in exchange for PI4P. Probably in a similar way, the glucosylceramide transfer protein FAPP2 may be recruited to DMVs to release lipids in exchange for PI4P into the DMV membrane. In this way cholesterol and sphingolipids would be enriched leading to the formation of lipid rafts likely required for HCV replicase activity and possibly the assembly of (lipidated) HCV particles.

Host Cell Factors Contributing to Various Steps of the HCV Replication Cycle

During the last few years, numerous host cell factors affecting the HCV replication cycle have been identified, but only a few can be mentioned here. The first one is microRNA-122 (miR122). The best-known role of miRNAs, which are short single-strand, non-coding

RNA molecules (20–24 nucleotides long) is the downregulation of protein expression by translational repression of the target mRNA or promotion of its cleavage. The HCV genome contains several conserved binding sites for miR-122, the most abundant miRNA in the liver. However, in contrast to its canonical function in the case of HCV, binding of miR-122 to two sites in the 5' UTR increases viral RNA translation and replication primarily via two different mechanisms. First, miR-122 forms an extensive Argonaute-2-containing oligomeric complex at the 5' end of the HCV genome and protects this RNA from nucleolytic degradation by the cellular 5'-to-3' exoribonuclease 1 (Xrn1) and Xrn2. Second, binding of miR-122 suppresses the formation of energetically favorable structures of the 5' UTR interfering with IRES activity, thus promoting RNA translation, which in turn interferes with viral RNA replication.

Another host factor essential for HCV replication is the prolyl-peptidyl *cis-trans* isomerase cyclophilin A (CypA). Binding of CypA to the HCV NS5A protein appears to catalyze the isomerization of peptidyl-prolyl bonds in NS5A domain I and domain II, resulting in conformational changes that stimulate NS5A RNA binding and enhance viral replication. CypA activity also seems to be required for the formation of an HCV replication organelle, as deduced from the observation that CypA antagonists block *de novo* formation of the membranous web.

A third important factor is SEC14L2, a cytosolic lipid-binding protein family member, which emerged as an important HCV host dependency factor. It was shown that ectopic expression of SEC14L2 enhances the replication of patient-derived HCV isolates in diverse human hepatoma cell lines that do not express this factor. This enhancement might be linked to the capacity of SEC14L2 to increase the accumulation of intracellular vitamin E protecting HCV from the detrimental effects of lipid peroxidation.

As mentioned above, apolipoproteins, such as apolipoproteins A-I, B, C-I, and E are components of HCV virions. Of these, ApoE fulfills a dual function in the viral life cycle. First, ApoE interacts with HSPG, LDLR and SRB1 and facilitates virus entry; second, it interacts with NS5A and the envelope glycoproteins and contributes to infectious virus particle production. An association of ApoE with E1-E2 seems to be required for lipidation and maturation of HCV particles at a post-envelopment step (Fig. 3). However, this association can also happen extracellularly with secreted ApoE that is part of lipoprotein particles. Thus, it is possible that ApoE incorporation starts intracellularly during assembly and continues extracellularly after virus particle release.

Host Cell Lipids of Relevance to the HCV Replication Cycle

To accommodate the net increase of intracellular membrane surface and the lipidation of HCV particles, a *de novo* synthesis of membrane lipids is induced in HCV-infected cells, along with an inhibition of lipid secretion. Indeed, lipidomic profiling of HCV-infected cells revealed distinct alterations of the lipid composition of host cells, including elevated levels of phosphatidylcholines and polyunsaturated fatty acids. At least two lipid biosynthesis pathways are activated by HCV: First, the transcriptional induction of lipid biosynthesis-related genes via the sterol regulatory element-binding protein (SREBP) pathway. In this case, HCV infection triggers trafficking of the ER-localized inactive SREBP precursor to the Golgi where it is proteolytically cleaved by site 1 protease (S1P) and S2P. The released N-terminal fragment is transported into the nucleus and it activates the transcription of lipogenic factors such as the fatty acid synthase and 3-hydroxy-3-methylglutaryl coenzyme A reductase (HMG-CoA), which is a rate-limiting enzyme of the cholesterol biosynthetic mevalonate pathway. Second, the 3' UTR of the HCV RNA genome binds to the cytosolic RNA helicase DEAD box polypeptide 3 X-linked (DDX3X), activating a signaling cascade that promotes SREBP-mediated transcription. In addition, HCV may mobilize fatty acids from lipid droplets.

The strong dependency of HCV on lipids may explain the antiviral activity of inhibitors of distinct lipid biosynthesis pathways. For instance, treatment of cells containing replicating HCV RNA with lovastatin, an inhibitor of 3-hydroxy-3-methylglutaryl CoA reductase, or with an inhibitor of protein geranylgeranyl transferase I induced the disintegration of the HCV replication organelle. Moreover, fatty acids can inhibit or stimulate HCV replication, depending on their degree of saturation. While saturated and monounsaturated fatty acids stimulate viral replication, polyunsaturated fatty acids impair replication but enhance the production of infectious virions.

Activation and Inhibition of Innate and Adaptive Immunity by HCV

Both in cell culture, and in the majority of patients, treatment with IFN- α leads to a rapid and efficient block of HCV replication. This result is somewhat surprising given the high rate of persistence of HCV infections (50%–80%) and the finding that in the infected liver IFN-induced genes (ISGs) are activated. In several studies, it was concluded that HCV proteins such as the core or NS3 proteins interfere with various steps of IFN- α/β induced signaling and that some HCV proteins block individual IFN- α/β induced effectors. However, in primary human hepatocytes infected with HCV, a robust IFN response is induced and the virus is rapidly cleared. Thus, it is still uncertain whether HCV can block the IFN-induced antiviral defense. It also remains to be clarified by which mechanism IFNs block HCV replication.

Much better established is the mechanism by which HCV aggravates the induction of innate antiviral defense. Several studies have shown that the NS3 protease proteolytically cleaves mitochondrial antiviral-signaling molecule (MAVS) relaying the activation of retinoic-acid-inducible gene 1 (RIG-I) to IRF-3 phosphorylation. As a result, IRF-3 dependent genes are not expressed and cells remain sensitive to virus infection. Indeed, it was shown that HCV controls ISG activation in infected cells, including the production of IFN- λ , which is the predominant IFN type in hepatocytes. In contrast, in cells expressing a MAVS variant that cannot be cleaved by HCV ISG expression and IFN- λ secretion are not affected, concomitant with reduced HCV replication. Although these

results clearly show the control of the MAVS signaling pathway by HCV, in infected cells the virus induces a robust IFN response. This may be due to activation of the Toll-like receptor 3 (TLR3) pathway that is less efficiently controlled by HCV. It was found that double-strand HCV RNA, a replication intermediate, is sensed by TLR3 in HCV-infected cells, but released via exosomes from infected cells. Inhibition of exosome release leads to intracellular accumulation of double-strand RNA, enhancing TLR3 activation and thus, induction of IFN gene expression. Apart from that HCV RNA-containing exosomes appear to be sensed by dendritic cells, contributing to the activation of IFN production.

In addition to the innate cytokine response, a rigorous and multi-specific T cell response is critical for the control and elimination of HCV. Thus, a successful antiviral defense generally encompasses multiple MHC class-I and class-II restricted T cell epitopes and an efficient expansion of CD8⁺ and CD4⁺ T cells. In contrast, persistent infections are characterized by oligoclonal T cell responses, a low frequency of HCV-specific T cells and the induction of poorly neutralizing antibodies. The underlying reasons for the weak response in the majority of patients are not clear, but several possibilities are discussed. These include an impaired antigen presentation e.g., due to interference of HCV with dendritic cell function; a CD4⁺ T cell failure due to deletion or anergy; a mutational escape in important T and B cell epitopes; a functional impairment of HCV-specific CD8⁺ T cells. The mechanisms underlying T cell attenuation are unclear, but one attractive possibility is that the defect induced in innate immunity may result in a defect in CD4⁺ T cell help. In fact, HCV-induced loss of T cell help appears to be the key event of immune evasion. In any case, CD8 T cells in chronic hepatitis C patients are exhausted, but this defect is partially restored in patients that have eliminated the virus in the course of antiviral therapy. This observation clearly shows that continuous HCV replication is required to suppress HCV-specific adaptive antiviral response, although an immunological “scar” remains upon virus elimination.

The role of HCV-specific antibodies in controlling viral infection is much less clear. Antibodies are probably less important for viral clearance and in most cases they do not protect from reinfection, neither in experimentally infected chimpanzees nor in humans, even after multiple exposure to HCV. However, there is increasing evidence that the presence of HCV-specific antibodies at least partially attenuates infection. For instance, antibodies neutralizing HCV particles of different genotypes have been detected in sera of chronic hepatitis C patients but the frequency of these antibodies is low. Nevertheless, in-depth studies of selected individuals who spontaneously cleared HCV infection have led to the identification of broadly neutralizing antibodies (bNAbs). In combination with the recently solved crystal structure of the E2 ectodomain, important contact sites between bNAbs and regions in E2, which are of relevance for neutralization across genotypes and subtypes, can now be identified, which should pave the way for the development of a prophylactic HCV vaccine.

Epidemiology

HCV is mainly transmitted by parenteral exposure to blood, blood products and objects contaminated with blood. The development of effective screening tests for blood and blood products and the implementation of viral disinfection procedures have almost excluded this route of transmission in countries where these measures are in place. Thus, the major remaining risk factor for acquiring HCV infection in developed countries is the use of contaminated needles in injection drug use and certain type of risk behavior. In some countries (e.g., Egypt) HCV infection has spread primarily by the use of inadequately sterilized medical instruments. In contrast to HBV infection, sexual transmission, and vertical transmission of HCV are much less frequent.

Modeling of HCV prevalence indicates that 71 million people (62.5–79.4) in 2015 were living with chronic HCV infection, accounting for approximately 1% of the world population. Prevalence rates vary significantly between and within countries. China, Pakistan, India, Egypt, Russia, and the USA have the highest number of cases, corresponding to around 50% of global HCV disease burden. However, only 20% of HCV-infected individuals have been diagnosed. Although the total number of HCV infections is declining since 2007, there are regions in the world where the prevalence is increasing. The reasons for this increase include unsafe health-care-related injections (e.g., Azerbaijan, India, Iraq, Syria, Uzbekistan), i.v. drug use (e.g., Iran, Russia, Latvia, and the USA), or immigration from endemic countries (e.g., Qatar, United Arab Emirates). Of note, in 2015 the number of people dying from HCV-related liver cirrhosis and hepatocellular carcinoma (~400,000) and being cured (~850,000) was exceeded by the number of newly infected persons (~1.75 million). Therefore, the HCV pandemic is continuing unless efficient interventions are scaled-up and implemented globally.

Clinical Features

Acute HCV infections are usually asymptomatic, or in about 30% of cases associated with non-specific symptoms such as abdominal pain, fatigue, weakness, poor appetite, nausea and icterus (Fig. 4). During an incubation period of 15–75 days, HCV RNA becomes detectable in serum by RT-PCR and virus titers usually peak to 10⁵–10⁷ genome equivalents/mL between week 6 and 10, irrespective of disease outcome (Fig. 4(A)). Two to four weeks after onset of viremia, serum ALT (alanine aminotransferase) levels begin to rise indicative of hepatocellular injury. Due to these uncharacteristic symptoms, acute HCV infection remains often unrecognized and therefore, undiagnosed. Only 20%–50% of infected individuals clear the infection, with those having a clinically overt acute infection having a higher chance to clear HCV, arguing that pathogenesis is driven mainly by the immune response.

Fig. 4 Course of acute and chronic HCV infection. (A) In acute HCV infection viral RNA is typically detectable between week 2 and 10 after virus exposure. ALT levels rise between week 4 and 10, peaking around week 6. By this time, the first symptoms manifest. HCV-specific antibodies arise late in infection. In self-limiting infection, HCV is cleared and anti-HCV antibodies may wane within years after resolution. (B) In chronic hepatitis C infection the early phase is similar to acute infection but later on, the virus persists. In the chronic phase, ALT levels fluctuate as does viremia. Antibodies against different HCV proteins are constitutively detectable.

While the duration of viremia in acute hepatitis C is unpredictable and can vary between 2 to 4–6 months, some patients even become HCV RNA negative during early convalescence, but later on viremia rebounds. Overall 50%–80% of HCV infections lead to a chronic carrier state (Fig. 4(B)). About 30% of these chronically infected persons progress to liver cirrhosis within 10–30 years after primary infection and hepatocellular carcinoma (HCC) occurs in up to 2.5% of these patients. In contrast to chronic hepatitis B, in persistent HCV infection HCC develops only to those patients, who have developed liver cirrhosis.

Pathogenesis

HCV infection is most likely not cytolytic. Instead, hepatocyte destruction is mediated by the immune response, arguing that HCV, like HBV infection, causes an immune pathology. Since hepatocytes are the primary target of HCV infection, the histological alterations of chronic hepatitis C are hepatocellular injury, portal and parenchymal inflammation and necrosis. Liver damage is typically spotty and focal with accompanying chronic inflammatory cells, including macrophages, and the disease eventually develops to a variable degree of fibrosis. The progression rate to hepatic fibrosis is the major determinant for the outcome of chronic hepatitis C in terms of developing cirrhosis and HCC. Although the liver is the primary target, persistent HCV infection is often associated with extrahepatic symptoms like renal complications, lymphoma and diabetes. A high proportion of patients with chronic hepatitis C develop cryoglobulinemia, which may account for some of these extrahepatic manifestations.

The mechanisms underlying HCV-associated tumorigenesis are poorly understood, but they are thought to arise from a combination of indirect and direct mechanisms. The most important indirect effect is a chronic inflammation, sustained at least in part by the antiviral immune response that attacks and destroys hepatocytes, yet this response is unable to eradicate the virus and eliminate the infection. Amongst the more direct effects are: (1) a possible reduction of the tumor suppressor miR-122 in infected cells due to binding to viral RNA and sequestration of miR-122 from normal cellular target RNAs; (2) a possible oncogenic effect of HCV core protein that has been observed in certain transgenic mouse models; (3) an elevated expression of EGFR, induced by HCV infection and playing an important role in HCC development; (4) the binding of NS5B to the tumor suppressor Rb, resulting in Rb degradation via the ubiquitin-proteasome pathway simultaneously with stimulation of hepatocellular proliferation. (5) persistent changes of the epigenome of infected cells.

Diagnosis

Routine screening tests for detecting HCV infections are based on serological assays measuring HCV specific antibodies (most often by ELISA or similar immunoassay) and nucleic acid-based tests (NAT) such as RT-PCR to determine viral RNA. Current serological assays have a specificity of >99% and they are positive in 99% or more of immunocompetent patients where viral RNA is detectable. Once a patient is tested positive in a serological assay, the sample should be tested by RT-PCR. A seropositive person with a positive PCR test result may have an acute, or, much more likely, a chronic HCV infection. A seropositive person with a negative PCR test result might have had an early or eliminated infection, a false negative test result, or a false positive serologic test result, or a chronic HCV infection with a very low viremia at the time of blood sampling. Thus, repeated testing is required in those cases.

Given the higher sensitivity, the diagnostic window can be reduced by using NAT. Quantitative RNA detection assays have been implemented in many blood banks e.g., in the EU and the US. The risk to acquire a transfusion-associated hepatitis C in such countries has been reduced to less than 1 in a million blood donations. The determination of HCV genotypes, which is an important parameter for IFN-based antiviral therapy, is based on analyzing viral RNA either by hybridization or direct sequence analysis or by using genotype-specific primers for RT-PCR. In addition to NAT, other (direct) detection methods of HCV have been developed, including the quantitative detection of HCV core protein. However, these assays are not widely available.

Treatment

For many years, antiviral therapy of chronic hepatitis C was based on the combination of a polyethylene glycol (PEG) conjugated form of IFN- α with ribavirin resulting in an overall sustained viral response (SVR) rate of ~60% in eligible patients. However, the success rate depended very much on two important parameters. The first one was the genotype of the infecting virus. While up to 85% of genotype 2- and 3-infected patients developed SVR, only around 45% of patients infected with genotype 1 viruses did so. In addition, this therapy had numerous serious side effects, including neuropsychiatric symptoms and hemolytic anemia, and therefore, many patients were either not eligible for this treatment or had to discontinue the therapy. The second parameter determining the success of IFN therapy is 3 distinct SNPs near the IFN- λ 3 and - λ 4 genes. While the causality between HCV infection and these SNPs remains to be determined, they appear to be of predictive value for other diseases including nonalcoholic fatty liver disease or infections with cytomegalovirus or HIV.

The limitations of IFN-based therapy of chronic hepatitis C have been overcome by the implementation of all-oral IFN-free direct acting antiviral drugs (DAAs) in 2014. These drugs allow virus elimination in >95% of individuals within a treatment period of 8–12 weeks; they are well tolerated and can be given to patients even with a decompensated liver cirrhosis. DAAs are targeting three viral proteins (Fig. 5): the NS3 serine protease, the NS5A replicase and assembly factor, and the NS5B RdRp. Numerous drugs against these three targets have been developed and although the drug names are complicated, the drug target is disclosed in the name. Protease inhibitors are ending with “-previr”, NS5A inhibitors with “-asvir”, and NS5B inhibitors with “-buvir”. While most of the first generation DAAs had a rather low resistance barrier, this limitation has been overcome with 3rd generation DAAs that are also rather pan-genotypic. Therefore, the first-line treatment of hepatitis C patients is based on a combination of at least two DAAs, e.g., a protease and a NS5A inhibitor or in addition a NS5B inhibitor (Fig. 5).

Although IFN-free DAA treatment has been in use for just a few years, it is becoming clear that the incidence of end-stage liver disease caused by HCV infection is declining with patients that mount a SVR. However, it is also becoming clear that in patients with advanced cirrhosis, HCV elimination is of limited use to prevent HCC because these patients still have a high risk for liver tumor development. While this observation argues for a “point-of-no-return” beyond which the presence of HCV is no longer relevant for HCC development, at the same time it has become clear that antiviral therapy should be given as early as possible to HCV infected individuals and not be limited to people with advanced liver disease. Fortunately, the price of the DAA therapy is reducing enabling the treatment of a larger proportion of HCV infected individuals.

Prevention

With the advent of highly efficacious DAAs global eradication of HCV has been considered as a reachable goal. While this is theoretically possible, major limitations need to be overcome. These include the limited availability of DAAs in many countries, the still high costs for these drugs, the insufficient health care systems in many high-endemicity countries and the fact that only a small proportion of HCV infections have been diagnosed. Moreover, reinfections with HCV are common, especially in high-risk populations such as intravenous drug users, and the number of new infections is rising, e.g., as a result of the opioid crisis in the USA (see above). For these reasons, global eradication strategies must not ignore the development of a prophylactic HCV vaccine. Although scientifically challenging, effective immunization against HCV appears to be feasible. Both in experimentally infected chimpanzees and in humans a rigorous and multi-specific T cell response can be induced and some individuals develop cross-neutralizing antibodies. What we need is a better understanding of the correlates of immune protection and how to induce a protective immune response with an ideal vaccine formulation. Thus far, only two vaccine candidates have been pursued in clinical trials. The first one is a recombinant envelope glycoprotein prophylactic vaccine that induced sterilizing immunity against experimental challenge of chimpanzees with a homologous HCV strain and reduced chronicity upon challenge with a heterologous strain of the same genotype. The second vaccine candidate is based on an adenovirus vector encoding an HCV NS3–5B polyprotein fragment used to prime the immune response, followed by a boost with a modified vaccinia Ankara (MVA) vector encoding the entire genome of the same HCV type. This combination, aiming to prime and boost CD4 and CD8 T cell responses, was found to be safe and to induce polyfunctional, broad HCV-specific memory CD4 and CD8 T cells. However, in a recent phase 2 clinical trial this vaccine failed to reach clinical significance in reducing the incidence of chronic HCV infection compared to placebo among HCV-uninfected intravenous drug users. Therefore, further efforts are required to identify vaccine candidates inducing a protective immune response. Without such a vaccine, achieving global eradication of chronic HCV infection is questionable.

Fig. 5 Drug targets and direct acting antiviral drugs (DAAs) for treatment of HCV infection. Ribbon diagrams of the 3D structures of the NS3/4A protease complex, the homodimer of NS5A domain I and the NS5B RdRp domain are displayed on the top. Shown are the NS3 protease domain (light blue) complexed with the NS4A peptide (orange) and Boceprevir (red); the NS5A domain I dimer with monomers represented in red and green; the NS5B RdRp domain complexed with UTP (yellow). DAAs targeting each of these proteins and clinically used drug combination therapies are given below each viral protein. Protein structures are derived from Protein data bank (PDB) accession 2OC8 for NS3/4A, PDB accession 1ZH1 for NS5A and PDB accession 1GX6 for NS5B.

Glossary

Animal Reservoir A large animal population serving as a source of virus supply for the transmission of viruses to other animals including humans.

Fulminant hepatitis A clinical condition characterized by massive necrosis of liver parenchyma and decrease in liver size that is usually caused by hepatitis virus infections or drug and toxin-induced liver injury.

Quasi-enveloped virus particles Non-enveloped viruses but present as membrane-wrapped quasi-enveloped virions

in the blood of infected hosts. As a non-enveloped virus, hepatitis E virus is present in multivesicular body as membrane-associated quasi-enveloped particles with intraluminal vesicles resembling exosomes in infected cells and blood.

Zoonotic infection Infectious diseases transmissible under natural conditions from vertebrate animals to humans.

Classification

Hepatitis E virus (HEV) is classified in the family of *Hepeviridae*, which comprises two genera. The genus *Orthohepevirus* includes all mammalian and avian hepatitis E virus isolates, whereas the genus *Piscihepevirus* consists of the cutthroat trout virus. Within the genus *Orthohepevirus*, there exist four distinct species: *Orthohepevirus A* consisting of HEV isolates from human, wild and domestic pigs, deer, mongoose, rabbit, and camel, *Orthohepevirus B* comprising avian HEV isolates from birds, *Orthohepevirus C* containing HEV isolates from rat, greater bandicoot, Asian musk shrew, ferret and mink, and *Orthohepevirus D* including HEV isolates from bat (Table 1).

HEV isolates known to infect humans all belong to the species *Orthohepevirus A*, which consists of at least 8 distinct genotypes. Genotype 1 HEV (mostly Asian isolates) and genotype 2 HEV (a Mexican isolate and some African isolates) infect only humans, whereas genotypes 3 (human, pig, rabbit, deer, mongoose), and 4 (human and pig) HEVs infect humans and several other animal species. Genotypes 5 and 6 HEVs infect wild boars with unknown zoonotic potential. Genotype 7 HEV infects dromedary camels and reportedly a human, and the genotype 8 HEV infects Bactrian camel (Table 1).

Virion Structure

HEV is an icosahedral, spherical virus particle of approximately 32–34 nm in diameter. HEV particles secreted in bile and stool are non-enveloped, however, in circulating blood and in supernatant of infected cell culture, HEV appears as membrane-associated quasi-enveloped particles with intraluminal vesicles resembling exosomes that are infectious but resistant to antibody neutralization. The capsid protein encoded by ORF2 is the only known structural protein on the virion, although the majority of ORF2 protein in serum and supernatant of HEV-infected cell culture exists as a secreted form (ORF2^S) that is not associated with virions.

The virion of HEV is a $T=3$ icosahedral capsid lattice consisting of 180 copies of capsid protein with three functional domains: S (shell), M (middle), and P (protruding). The S domain forms the icosahedral shell, while the P domain is the binding site for an unknown cellular receptor. The M domain interacts with S and P domains contributing to virion stability. The virion buoyant density is 1.35–1.40 g/cm³ in CsCl, and 1.29 g/cm³ in potassium tartrate and glycerol. The virion sedimentation coefficient is 183S. The HEV virion is more heat labile than is hepatitis A virus (HAV), another enterically transmitted hepatitis virus. Infectious HEV was still detectable after incubation at 37°C for 21 days, at room temperature for 28 days, and at 4°C for 56 days with a 2.7-log decrease of virus titer. Incubation of infectious virus at 60°C for 1 min resulted in moderate decreases in infectivity, 2- to 3.5-log decreases in infectivity between 65°C and 75°C for 1 min, and complete inactivation at $\geq 80^\circ\text{C}$ for 1 min. The fecal-oral route of transmission indicates that HEV is resistant to inactivation by acidic and mild alkaline conditions in the gastrointestinal tract.

Genome

The genome of HEV, which possesses a 7-methylguanosine cap structure at its 5' end, is a single-stranded, positive-sense RNA molecule of approximately 7.2 kb in length. The genome consists of a short 5' noncoding region (NCR), three open reading frames (ORFs 1, 2, and 3), and a 3' NCR. ORF3 overlaps ORF2, but neither overlaps ORF1 (Fig. 1). The ORF1 encodes nonstructural proteins responsible for viral replication and protein processing. Functional domains within ORF1 have been identified, including methyltransferase (Met), papain-like cysteine protease (PCP), hypervariable region (HVR) or proline rich region (PRR), X (or

Table 1 Host range of hepatitis E virus and zoonotic infection in humans^a

Natural animal host	Classification [genus/species, genotypes (gt)]	Experimental hosts for cross-species infection	Zoonotic infection in humans
<i>Orthohepevirus A</i>			
Human	gt 1, 2, 3, 4	Non-human primates, pigs (gt3, gt4), rabbit (gt1, gt4), lamb (gt1), Wistar rats (gt1)	
Domestic swine	gt 3, 4	Non-human primates, rabbit, Mongolian gerbil (gt4), Balb/C mice (gt3, gt4)	Yes
Wild boar	gt 3, 4, 5, 6		Yes (gt 3, 4), likely (gt 5, 6)
Deer	gt 3		Yes
Rabbit	gt 3	Pig	Yes
Mongoose	gt 3		Likely
Dromedary camel	gt 7	Non-human primates	Yes
Bactrian camel	gt 8	Non-human primates	Unknown
Moose	unknown		Unknown
<i>Orthohepevirus B</i>			
Chicken, wild birds	aHEV gt 1, 2, 3, 4	Turkey	No
<i>Orthohepevirus C</i>			
Rat			Yes
Ferret			Unknown
Greater bandicoot			Unknown
Asian musk shrew			Unknown
Mink			Unknown
Common kestrel			Unknown
Red-footed falcon			Unknown
Bat	<i>Orthohepevirus D</i>		No
Cutthroat trout	<i>Piscihepevirus</i>		No

Fig. 1 A schematic diagram of comparative genomic organization of mammalian, avian, and fish HEVs. The three open reading frames (ORFs) are labeled and shown as boxes. ORF2 overlaps ORF3 but neither overlaps ORF1. ORF1 encodes nonstructural proteins with the putative functional domains indicated inside the box. ORF2 encodes the capsid protein, and ORF3 encodes a small multifunctional protein that is involved in virus replication. The HEV genome is capped (m7G Cap) at the 5' end, and contains a poly A tail at the 3' end. There are noncoding regions (NCR) at the 5' and 3' end of the viral genome. There is a junction region between ORF1 and ORF3 for mammalian and avian HEVs, which contains a stem-loop structure and a *cis*-reactive element (CRE). The avian HEV genome is approximately 600 bp smaller than the mammalian and fish HEVs. Hel, helicase; HVR, hypervariable region; MT, methyltransferase; NCR, noncoding region; P, a papain-like cysteine protease; RdRp, RNA-dependent RNA polymerase; X, macro domain. Reproduced from Meng, X.J., 2016. PLoS Pathogens 12(8), e1005695. doi:10.1371/journal.ppat.1005695, which was published under a Creative Commons License.

macro) domain, helicase (Hel), and RNA-dependent RNA polymerase (RdRp) (Fig. 1). An RNA element located in the 5' end region of the ORF1 binds to capsid protein and is thought to be the RNA packaging signal. The viral genomic RNA contains two *cis*-reactive RNA elements (CREs) important for virus replication. CRE1 overlaps the 3' end of ORF2 and continues into the 3' NCR, and forms two stem-loop structures that interact with RdRp. CRE2 locates in the intergenic junction region between ORF1 and ORF3, and forms a stem-loop structure that is part of the promoter for synthesis of the subgenomic RNA. The intragenomic

subgenomic promoter regulating subgenomic RNA synthesis is mapped to the junction region extending to the 3' end of ORF1. Both the sequence and the stem-loop structure in the junction region play important roles in HEV replication.

ORF2 encodes capsid protein that contains a signal peptide sequence, and three glycosylation sites. The capsid protein contains an immunogenic epitope, induces neutralizing antibodies against HEV, and is the target for vaccine development. A secreted form of ORF2 protein (ORF2^S) is translated from an AUG start codon that is 15 amino acids upstream to the N terminus of the capsid protein. The ORF2^S does not block HEV cell entry but inhibits antibody-mediated neutralization. ORF3 encodes a small cytoskeleton-associated phosphoprotein. The N-terminus of ORF3 has a cysteine-rich region, binds to HEV RNA, and enters into a complex with the capsid protein. The C-terminus of ORF3 is a multifunctional domain involved in HEV virion morphogenesis and pathogenesis. The ORF3 is essential for virus infectivity in vivo, although it is not required for virion assembly or infection of hepatocellular carcinoma cells in vitro. Overlapping the macro and Hel domains in genotype 1 HEV, but not other HEV genotypes, is a small frameshifted ORF4 that is controlled by an internal ribosome entry site (IRES)-like RNA structure, which induces ORF4 protein translation under endoplasmic reticulum (ER) stress.

Life Cycle

Attachment and entry: The attachment and entry of HEV into susceptible cells remains largely unknown, due in large part to the lack of an efficient cell culture system to propagate HEV. The capsid protein attaches to susceptible cells via heparin sulfate proteoglycans (HSPGs) to facilitate HEV entry, although a specific receptor for HEV has not yet been identified. The virions are internalized through a clathrin and dynamin-2 based pathway. The entry of quasi-enveloped HEV particles reportedly involves the small GTPases Rab5 and Rab7 and degradation of the quasi-envelope membrane within the lysosome. The uncoating process of the capsid is not understood, although the P domain of the capsid contains polysaccharide binding sites that may be involved in capsid disassembly to facilitate the uncoating process.

Transcription and translation: Upon uncoating and delivering the viral genomic RNA to the cytosol, the ORF1 polyprotein is translated directly from the positive-sense viral genomic RNA by cap-dependent translation, and eukaryotic translation initiation factors 4A, 4G, and 4E are involved in HEV replication. Whether the ORF1 polyprotein requires further processing for functionality remains debatable, since contradictory results have been reported with some studies showing no processing at all while others reporting cleaved products corresponding to the sizes of Met, Hel, and RdRp. The ORF2 and ORF3 proteins are also translated in a cap-dependent fashion from a single bicistronic subgenomic mRNA by a process involving leaky ribosome scanning in which ribosomes bypass the ORF3 initiator AUG to initiate protein synthesis downstream at the ORF2 AUG initiator codon.

Replication of viral genome: The replication of HEV genome involves the transcription of a negative-sense replicative RNA intermediate by viral RdRp. This negative-sense RNA subsequently serves as the template for the production of the positive-sense, progeny viral genomic RNA as well as the bicistronic subgenomic mRNA. In HEV-infected animal tissues, the negative-sense replicative RNA intermediate has been detected by negative strand-specific RT-PCR. A viral replication complex (VRC) forms on ER membranes or on vesicles consisting of ER-derived membranes, although the VRC composition is not well understood. For genotype 1 HEV, the VRC appears to contain the ORF4 protein, Hel, RdRp, and macro domains of ORF1, along with host eukaryotic elongation factor 1 isoform-1 (eEF1 α 1) and tubulin β .

Assembly and release: Little is known about the assembly and release steps in the life cycle of HEV. The capsid protein packages the HEV genome through binding to a putative RNA packaging signal located in the 5' end region of the viral genome. Binding of viral RNA to the N-terminus of capsid leads to the formation of C-terminal/C-terminal dimers that are important for completing viral capsid assembly. It has been shown that ORF3 is involved in viral egress via interaction with host late domain proteins. Quasi-enveloped HEV has been detected within multivesicular bodies (MVBs) associated with trans-Golgi network protein 2 and CD63, suggesting that HEV capsids bud into intracellular vesicles requiring the MVB pathway to release virions. The ORF3 protein is a viroporin forming a functional ion channel at plasma membrane to facilitate the release of infectious virus particles.

Epidemiology

Morbidity and mortality: In developing countries, a high seroprevalence of HEV antibodies was reported. For example, more than 70% of the general populations in Egypt are seropositive for HEV antibodies. Surprisingly, in some industrialized countries where clinical cases of hepatitis E are rare, the seroprevalence of HEV antibodies is much higher than expected, with up to 30% seropositivity in blood donors in the United States. The morbidity for hepatitis E is not very reliable due in large part to the lack of accurate etiology-specific data for acute viral hepatitis. Most sporadic cases of acute viral hepatitis are not routinely tested for HEV and thus are not reported. Historically, the incidence of hepatitis E in large outbreak settings was estimated at 1400–1650 per 100,000 population in India and Nepal. More recently, a large outbreak of 2621 cases of acute hepatitis E was reported in refugee camps in Darfur, Sudan with an attack rate of 3.3% and a case-fatality rate of 1.7%. The highest attack rate of clinical disease is generally in young adults of 20–29 years of age, although the seroprevalence of HEV antibodies is age-dependent and increases with age. HEV-associated mortality in the general population is <1% but it can reach up to 25% in infected pregnant women. According to the World Health Organization, annually there are an estimated 20 million HEV infections worldwide leading to approximately 3.3 million cases of hepatitis E with >44,000 HEV-related deaths.

Animal reservoirs and cross-species infection: Since the discovery of the first animal strain of HEV, swine HEV, from pigs in the United States, genetically-diversified strains of HEV have now been identified from more than a dozen other animal species including chicken, deer, mongoose, rabbit, rat, ferret, moose, shrew, kestrel, egret, bat, goat, camel, and cutthroat trout. The ecology, natural history, zoonotic potential and pathogenicity for most of these animal hepeviruses are still largely unknown, although the genotype 3 HEV infecting pig, rabbit, deer and mongoose, and the genotype 4 HEV infecting pigs are known to be zoonotic and infect humans.

Under natural conditions, zoonotic infections in humans by genotypes 3 and 4 HEVs from various animal species have been well documented. The sporadic and cluster cases of hepatitis E in humans from industrialized countries are caused primarily by the zoonotic genotypes 3 and 4 HEVs of animal origin. Cases of chronic hepatitis E in immunocompromised individuals are almost exclusively caused by the zoonotic genotype 3 HEV of animal origin. Pig caretakers such as farmers and swine veterinarians had a higher risk of zoonotic HEV infection. In addition to pigs, the zoonotic genotype 3 HEV has also been identified in rabbit, deer, and mongoose, suggesting that these animals are also reservoirs. Zoonotic transmissions of hepatitis E from deer to humans and from rabbit to humans have been reported. A genotype 7 camelid HEV also reportedly infected a human liver transplant recipient. More recently, human infections by rat HEV have also been reported.

Under experimental conditions, genotypes 3 and 4 HEVs can infect across species barriers: genotypes 3 and 4 swine HEVs infect rhesus macaques and chimpanzee, and conversely, genotypes 3 and 4 human HEVs infect pigs. Genotype 3 rabbit HEV was also shown to infect pigs and cynomolgus macaques. Balb/c nude mice are reportedly susceptible to experimental infection with a genotype 4 swine HEV, although others failed to infect C57BL/6 mice with genotype 1, 3 and 4 HEVs. Rabbits have been reportedly infected with genotypes 1 and 4 HEV, although independent confirmation is still lacking. Avian HEV infects turkeys, but not rhesus macaques, suggesting that avian HEV is not zoonotic.

Sources and risk factors of HEV infection: For epidemics, the main source of infection is HEV-contaminated drinking water in areas with poor sanitation such as villages in developing countries, and refugee camps. Hepatitis E epidemics are often associated with contamination of well water or leakage of untreated sewage into city water treatment plants, and poor sanitary conditions such as washing hands in a group basin. Person-to-person transmission of hepatitis E is not common during an epidemic. In contrast, the main sources for sporadic or cluster cases of hepatitis E appear to be contaminated animal meats, shellfish, and direct contact with infected animals.

Hepatitis E epidemics are mainly in developing countries of Asia, Africa, and Latin America, particularly in regions with hot climates or poor sanitation conditions. However, sporadic or cluster cases of hepatitis E occur in both developing and industrialized countries. A high incidence of hepatitis E outbreaks is observed in seasons with monsoon rains and flooding. The use of river water for drinking and cooking, washing, and disposal of human excreta carries a higher risk of HEV infection. Pigs are reservoirs for HEV, and therefore pig farmers, swine veterinarians and other pig caretakers in both developing and industrialized countries are at increased risk of HEV infection. In the United States, swine veterinarians were 1.51 times more likely to be seropositive for HEV antibodies than normal blood donors. Individuals from traditionally major swine states are more likely to be seropositive for HEV antibodies than those from traditionally non-swine States. Individuals with occupational exposure to wild animals also have an increased risk of zoonotic HEV infection. Sewage workers in India had a significantly higher seroprevalence of HEV antibodies (56.5%) than controls (19%), although such an association was not found in Switzerland. In a large hepatitis E outbreak in 2004 in refugee camps in Darfur, Sudan, the risk factors included age of 15–45 years (OR=2.13) and drinking chlorinated surface water (OR=2.49).

Transmission: HEV is primarily transmitted by fecal-oral route, although under experimental conditions it is rather difficult to infect non-human primates or pigs via oral route of inoculation. Waterborne transmission via sewage-contaminated drinking water and contaminated well or river water used for washing and drinking purpose is the main source of HEV infection in developing countries. Feces from infected animals contain large amounts of HEV leading to contamination of irrigation or coastal water with concomitant contamination of produce or shellfish. HEV strains of both human and swine origin have been detected in sewage water.

Foodborne transmission is responsible for most sporadic and cluster cases of acute hepatitis E that were linked to the consumption of raw or undercooked animal meats. Sporadic cases of hepatitis E were associated to the consumption of raw or undercooked wild boar meat deer meat, and pork products. HEV RNA was detected in commercial pork products sold in grocery stores, and the contaminating virus in commercial pig livers from grocery stores remains infectious. Raw pig liver sausages (figatelli) were the source for some sporadic and cluster cases of hepatitis E in France. Consumption of raw deer meats was responsible for cluster cases of acute hepatitis E in Japan. Also, HEV infections were linked to the consumption of contaminated shellfish and strawberries. Zoonotic transmission through direct contact with infected animals occurs for genotypes 3, 4 and genotype 7 HEVs within the species *Orthohepevirus A*. Potential transmissions of hepatitis E from a pet cat and a pet pig to human owners were also reported.

Vertical transmissions from mother-to-fetus associated with a high neonatal mortality has been reported. Among the 62 HEV-infected pregnant women, vertical transmission of HEV occurred in 33.3% of the cases. HEV RNA was detected in some cord blood and in colostrum of HEV-infected mothers, although breast-feeding appears to be safe for infants. Vertical transmission has been reported in HEV-infected human patients, but experimental evidence of vertical transmission of HEV in animal models is still lacking. Pregnant sows and pregnant rhesus monkeys experimentally-infected with HEV failed to transmit the virus to offspring. Egg whites from eggs of chickens experimentally infected with a chicken strain of HEV contain infectious virus, but evidence of complete vertical transmission is lacking.

Blood-borne transmission through blood transfusions, although not common, has been reported in patients worldwide. HEV RNA has been detected in a small proportion of blood donors in Japan and some European countries, thus raising a potential

concern of transfusion-transmitted hepatitis E. In Germany, HEV viremia was detected in approximately 0.12% of blood donors at a tertiary care center. In the United States, in one study HEV RNA was not detected in blood donors or recipients, while in a separate study three out of 128,020 blood donors from 27 states tested positive for genotype 3 HEV RNA. The incidence of viremia and viral loads in blood donors, and the total plasma volume the recipients receive are the determining factors for transfusion-associated HEV infection. It remains debatable as to whether donor blood should be screened for acute markers of HEV infection, although several European countries have already implemented HEV RNA screening of blood donors.

Clinical Features

The majority of HEV infections are subclinical, and a proportion of the infected individuals do develop self-limiting acute viral hepatitis, but the acute disease usually does not go into chronicity. However, in immunocompromised individuals, HEV infections can progress into chronic hepatitis E, which has become an emerging and significant clinical problem. Numerous neurological diseases such as Guillain-Barré syndrome and neuralgic amyotrophy have also been linked to HEV infection, although the underlying mechanism of neurological invasion by HEV remains unknown. Fulminant hepatitis E with a high mortality have been reported in HEV-infected pregnant women especially during the third trimester.

Self-limiting acute hepatitis E: Only a proportion of HEV-infected individuals develop self-limiting acute viral hepatitis. The incubation period typically ranges from 2 weeks to up to 2 months. The clinical symptoms of acute hepatitis E, which include Jaundice, anorexia, abdominal pain, nausea, vomiting, and fever, are essentially indistinguishable from those of other types of acute viral hepatitis. Viremia and fecal virus shedding are detectable approximately 3 weeks post-infection and 1 week prior to the onset of clinical disease. A transient appearance of IgM HEV antibodies followed by long-lasting IgG antibodies appear late during the period of viremia and fecal virus shedding. The infected patients typically recover from acute hepatitis E and are protected against subsequent HEV infection.

Chronic hepatitis E: Although HEV generally causes a self-limiting acute viral hepatitis in immunocompetent individuals, the majority of HEV infections in immunocompromised individuals such as solid organ transplant recipients and patients with HIV/AIDS, lymphoma, or leukemia progress into chronic hepatitis E. Organ transplant recipients with chronic hepatitis E have persistently elevated aminotransferase levels, viremia, and hepatic lesions, and also shed HEV in feces for a prolonged period of time. Cases of chronic hepatitis E are almost exclusively caused by the zoonotic genotype 3 HEV, which infects pig, rabbit, deer and mongoose. Therefore, the source of chronic HEV infection is of zoonotic origin presumably through consumption of undercooked HEV-contaminated animal meats.

Under experimental conditions, aimed at mimicking the conditions of immunocompromised organ transplant patients, pigs were treated with an immunosuppressive regimen and experimentally infected with genotype 3 HEV. The infected pigs developed chronic HEV infection with fecal virus shedding lasting for at least 22 weeks post-infection. Active suppression of cell-mediated immune responses under immunocompromised conditions facilitates the establishment of chronic HEV infection. Similarly, cynomolgus monkeys treated with tacrolimus, an immunosuppressive drug, and experimentally infected with a genotype 3 swine HEV also developed chronic HEV infection with pronounced hepatic lesions at 160 days after infection.

Fulminant hepatitis with a high mortality during pregnancy: Accumulating evidence indicates that HEV infection during pregnancy causes fulminant hepatic failure with a high mortality. In India, one study showed that the mortality rate in HEV-infected pregnant women is 65.8% (25/38) due to fulminant hepatic failure. In another study, the mortality rate among the HEV-positive pregnant women was 27%, and approximately two-thirds of the infected pregnant women had preterm deliveries. However, in Egypt, a study of 2428 pregnant women did not link HEV exposure to a history of liver disease. Genotype 1 HEV is usually associated with fulminant hepatic failure in infected pregnant women, although zoonotic genotypes 3 and 4 HEVs are also associated with fulminant hepatic failure.

Under experimental conditions, however, severe and fulminant hepatitis could not be reproduced in pregnant pigs or monkeys: pregnant sows experimentally infected with genotype 3 HEV had no clinical signs of hepatitis or elevation of liver enzymes. Similarly, pregnant rhesus macaques experimentally infected with genotype 1 HEV did not develop more severe hepatitis than non-pregnant monkeys. Recently, however, fulminant hepatitis with high mortality was successfully reproduced in genotype 3 rabbit HEV-infected pregnant rabbits. Fetal mortality rates ranging from 67% to 80% were observed. Miscarriages, high fetal and maternal mortality, and fulminant hepatitis were also reproduced in these genotype 3 rabbit HEV-infected pregnant rabbits. The underlying mechanism of fulminant hepatitis with high mortality during pregnancy is still unknown, although the social economic status of the patients, hormonal changes during pregnancy, immunological status of the patients, and the existence of other co-infecting agents in patients could all play a potential role.

Neurological diseases: Neurological diseases such as Guillain-Barré syndrome, neuralgic amyotrophy, encephalitis, and myelitis have been associated with zoonotic genotype 3 HEV infection and, to lesser extent, genotypes 1 and 4 HEV infections. Guillain-Barré syndrome and neuralgic amyotrophy are associated with HEV infection in approximately 5% and 10% of the cases, respectively. In some patients, HEV RNA was detected in cerebrospinal fluid, indicating an infection of central nerve system. The neurological disorders in humans are mostly associated with infection by genotype 3 HEV that infects pig, deer, rabbit and mongoose, and occur during both acute and chronic HEV infections. Under lab conditions, numerous human neuronal-derived cell lines have been shown to support HEV replication. In animals peripherally infected with HEV, viral RNA and antigen were detected in brain tissues. The available data thus far suggest that HEV infects cells in the central nerve system leading to manifestation of various neurological diseases, which has become an emerging and significant clinical problem.

Pathogenesis

The mechanism of HEV pathogenesis is not well understood. HEV enters the host through the fecal-oral route. It is thought that, after oral ingestion of HEV, the virus first replicates in the gastrointestinal tract before reaching its target organ, the liver, via viremia. In pigs experimentally infected with human and swine HEVs, virus replication has been identified in small intestines, colon, hepatic and mesenteric lymph nodes, although the clinical significance of these extrahepatic sites of virus replication remains unknown. HEV replication in the liver has been detected in non-human primates, pigs and chickens experimentally infected with HEV. It is believed that, after replication in liver, HEV is released to the gallbladder from hepatocytes and is excreted in feces. Fecal virus shedding and viremia proceeds the onset of clinical and biochemical hepatitis, and virus shedding ends when the level of serum liver enzyme returns to baseline. In pigs experimentally infected with a genotype 3 human HEV, mild-to-moderate multifocal lymphoplasmacytic hepatitis and focal hepatocellular necrosis were observed. In chickens experimentally infected with an avian strain of HEV, gross lesions including subcapsular hemorrhages and slightly enlarged right intermediate lobe of the livers, and histological lesions including foci of lymphocytic periphlebitis and phlebitis were also observed.

Diagnosis

HEV serological assays are commercially available in some countries, although considerable variations in the specificity and sensitivity of these assays have been reported. These serological assays primarily use the recombinant ORF2 capsid protein or a mixture of both ORF2 and ORF3 proteins as the antigen. Some serological assays are approved for HEV diagnosis by regulatory agencies in Asia and Europe, however an FDA-approved diagnostic assay in the United States is still lacking. IgM anti-HEV is detectable in up to 90% of the acute HEV infections within 1–4 weeks after onset of the disease. IgG anti-HEV persists in infected individuals lasting from <1 year in some pediatric patients to 2–14 years in some adult patients.

RT-PCR and quantitative RT-PCR assays have also been developed to detect and quantify HEV genomes. However, significant variations in the sensitivity and specificity of these PCR-based assays were reported, largely due to the extensive heterogeneity of HEV. At least five genotypes of HEV, genotypes 1–4 and 7, within the species *Orthohepevirus A* are known to infect humans, thus stressing the need for a standardized universal PCR-based assay for HEV detection.

Treatment

Most HEV infections are self-limiting and acute in nature, and do not warrant antiviral treatment. However, a subpopulation of HEV-infected individuals, such as pregnant women with a high mortality and immunocompromised individuals with a high tendency of progressing into chronicity, do require antiviral treatment options. Currently there is no HEV-specific therapy, however broad-spectrum antivirals such as ribavirin and pegylated-interferon have been used with some success. Ribavirin monotherapy inhibits HEV replication and induces a sustained virus inhibition in patients with chronic HEV infections. Pegylated-interferon- α also induced a sustained antiviral response in HEV-infected patients. However, both ribavirin and interferon- α have severe side effects, and are contraindicated in pregnant women. Therefore, development of effective HEV-specific antivirals is warranted.

Prevention

A commercial vaccine based on the recombinant ORF2 capsid protein of a genotype 1 HEV has been licensed for use only in China but not elsewhere. Other experimental HEV vaccines based on the capsid protein also appear to be very promising. However, significant challenges remain for a more cost-effective modified live-attenuated vaccine due to the lack of an efficient cell culture system to propagate HEV. The practice of good hygiene and avoiding drinking water of unknown purity or consuming raw or undercooked animal meats are important preventive measures.

Glossary

Encephalitis Infection of the central nervous system.

Gingivostomatitis Infection of the oral cavity.

Innate immunity Immune responses induced by recognition of pathogen-specific molecular patterns.

Intrinsic resistance Host factors that are constitutively expressed and restrict infection.

Keratitis Infection of the cornea.

Latent infection An infection in which the viral genome can be detected but no infectious virus can be detected, but in which infectious virus can be reactivated upon appropriate stimuli.

Lytic infection An infection that produces progeny virus and leads to death and lysis of the infected cells.

Pro-drug A compound that is metabolized in the body to an active drug molecule.

Classification

Human herpes virus 1 (HHV-1), commonly known as herpes simplex virus 1 (HSV-1), and human herpes virus 2 (HHV-2), commonly known as herpes simplex virus 2 (HSV-2), are two species of viruses in the *Simplexvirus* genus in the *Herpesviridae* family of the *Herpesvirales* order. These two viruses are sometimes called type 1 and type 2, but they are formally species, so the word “type” is incorrect. Many of the genetic and phenotypic properties of HSV-1 and HSV-2 are similar, so we will describe them together as HSV where genes and mechanisms are shared by the two viruses.

Virion Structure

The HSV virion (extracellular virus particle) consists of the core containing the double-stranded DNA genome surrounded by an icosahedral capsid, enclosed by a largely unstructured protein layer (tegument), surrounded by the outer lipid bilayer membrane (envelope) which contains embedded glycoprotein spikes (Fig. 1). The core consists of the DNA wrapped as a toroid in a liquid crystalline state. The DNA has no associated histones, and the phosphate charges on the DNA may be neutralized by polyamines. The capsid is a protein shell comprised of four viral proteins assembled with icosahedral symmetry based on 162 capsomeres or structural units defining the 16 triangular faces on the icosahedron. Twelve of the capsomeres form the vertices, of which 11 are pentons (five-fold symmetry) and one is the portal, through which virion genomic DNA is inserted, while 140 of the capsomeres are hexons (six-fold symmetry) that form the faces of the icosahedral structure. The tegument is comprised of at least 18 viral proteins and is largely unstructured, although there is some evidence for icosahedral organization imposed by interactions with the capsid and some granular and filamentous character. The envelope is a lipid bilayer membrane derived from host cell membranes that has as many as 13 viral proteins embedded in it.

Genome

The HSV genome is a linear double-stranded DNA molecule of approximately 150,000 base pairs (bp) with a one bp 3' extension at each end. The virion DNA contains nicks and gaps and a G + C content of 68% for HSV-1 and 69% for HSV-2 DNA. The HSV-1 and HSV-2 genomes are largely collinear with many of the lytic genes being highly homologous. HSV-1 X HSV-2 recombinants are readily isolated with cross-over events throughout the genomes, further demonstrating the similarity of the HSV-1 and HSV-2 genomes.

The HSV genome can be considered to consist of two covalently linked components, the L (long) and S (short), each of which is bounded by inverted repeats. The termini of the molecules contain a short repeated sequence that is also present in inverted forms at the L-S junction. The inverted repeated sequences provide homology for recombination that results in inversion of the L and S components, relative to each other. As a result, virion and infected cell DNAs contain approximately equimolar populations of four isomers of HSV DNA that result from inversion of one component or the other or both. The reason for the inverted repeated sequences has not been defined, but they may play a role in recombination-mediated replication of the viral DNA genome.

Life Cycle

HSV undergoes a lytic productive infection in epithelial cells and fibroblasts when it is inoculated onto the oral (usually HSV-1) or genital (usually HSV-2 but increasingly HSV-1) mucosa (Fig. 2). The virus spreads and causes the primary herpetic lesion. The virus

Fig. 2 Stages of herpes simplex virus (HSV) infection of the host. A: HSV is introduced onto a mucosal surface or a break in the skin, and it replicates productively in epithelial cells at the site of inoculation and spreads through the tissue. Virus enters sensory neuron axons and is transported to the cell body in a ganglion. B: HSV establishes a latent infection in the neuronal cell nucleus. Viral DNA is circular and assembled in chromatin. C: Upon neuronal damage or activation, the virus reactivates and undergoes at least a limited productive cycle. Capsids are transported by anterograde transport to the axonal termini, and virions are released. Reactivated virus causes a recurrent infection of the mucosal tissue, causing the shedding of virus. Copyright, Patrick T. Waters and David Knipe.

enters the axons of sensory neurons and establishes a latent infection in the neuronal cell body. Upon stress or damage to the neuron, the virus reactivates and causes the recurrent infection.

Lytic Infection

HSV lytic infection of epithelial cells or fibroblasts is initiated by binding of the virion to the cell surface and entry by fusion at the plasma membrane (Fig. 3, step 1a) or endocytosis followed by fusion in an endosome (Fig. 3, step 1b). The nucleocapsid and tegument are transported along microtubules (Fig. 3, step 2) to the nucleus where the capsid docks at the nuclear pore and releases the virion DNA into the nucleus. The input genome rapidly circularizes (Fig. 3, step 5) and is loaded with histones by host cell mechanisms. Virion protein 16 (VP16) localizes into the nucleus (Fig. 3, step 4) and assembles a complex of host proteins that promote transcription of the immediate-early (IE) mRNAs (Fig. 3, step 6). The IE mRNAs are transported to the cytoplasm where they are translated to yield the five IE proteins. Four of the five proteins localize to the infected cell nucleus where they promote early (E) and late (L) gene transcription. The E mRNAs are transported to the cytoplasm where they encode the E proteins, including seven viral proteins directly involved in viral DNA synthesis and other proteins that increase deoxynucleotide triphosphate levels for viral replication in resting cells. The E viral DNA polymerase and thymidine kinase (TK) are the targets of the nucleoside analogs used for antiviral therapy as described below.

The seven essential viral proteins together with host proteins replicate the input viral genome to yield progeny viral genomes as concatemers (Fig. 3, step 8). Replication of the viral DNA is thought to occur in two stages: (1) Cairns circle replication of the input viral genome, and (2) rolling circle and/or recombination-based replication generating concatemeric progeny molecules of viral DNA. Following initiation of viral DNA synthesis, the replicative intermediates and progeny DNA molecules serve as substrates for

Fig. 3 Diagram of the replication cycle of herpes simplex virus. 1: The virus binds to the cell plasma membrane and the virion envelope fuses with the plasma membrane (1a) or the virus enters by endocytosis (1b), releasing the capsid and tegument. proteins into the cytoplasm. 2: The capsid is transported to the nuclear pore, where the viral DNA is released into the nucleus. 3: The vhs (virion host shutoff) protein causes degradation of host messenger RNAs (mRNAs). 4: VP16 localizes into the nucleus. 5: The viral DNA circularizes. 6: It is then transcribed by host RNA polymerase II to give first the immediate-early (IE) mRNAs. Gene transcription is stimulated by the VP16 tegument protein. Five of the six IE proteins act to regulate viral gene expression in the nucleus. 7: IE proteins transactivate early (E) gene transcription. 8: The E proteins are involved in replicating the viral DNA molecule. 9: Viral DNA synthesis stimulates late (L) gene expression. 10: The L proteins are involved in assembling the capsid in the nucleus and modifying the membranes for virion formation. 11: DNA is encapsidated in the capsid. 12: The filled capsid buds through the inner membrane to form an enveloped virion, and the virion exits from the cell by mechanisms described in the text. Copyright, Patrick T. Waters and David Knipe.

transcription of the L genes (Fig. 3, step 9). The L mRNAs are translated in the cytoplasm to yield structural proteins for assembly of progeny virions. The capsid proteins localize into the infected cell nucleus and assemble empty capsids (Fig. 3, step 10), and viral DNA is inserted into the capsid through the portal on the capsid (Fig. 3, step 11). Once the capsid is filled with approximately a unit-length of viral DNA, the concatemeric DNA is cleaved and the portal is plugged. Some tegument proteins are localized into the nucleus and inner nuclear membrane to promote budding of the nucleocapsid through the inner nuclear membrane. Egress of the virion from the host cell (Fig. 3, step 12) is thought to then involve a complicated pathway involving primary envelopment at the inner nuclear membrane, de-envelopment of the virus particle at the outer nuclear membrane, and then secondary envelopment at membranes of the Golgi apparatus. The enveloped virion then travels out of the cell by the secretory pathway.

Viral DNA replication, late gene transcription, and viral DNA encapsidation take place within virus-specific nuclear structures called replication compartments (Fig. 3, steps 8–10). The concentration of viral host factors in these factories is thought to enhance the rate of the reactions, as well as possibly provide a platform for the viral processes. The accumulation of viral nucleic acid and capsids in the replication compartments gives rise to the nuclear inclusion bodies that show specific staining properties characteristic of herpesviral infection.

The process of lytic infection involves the viral gene products inhibiting host cell metabolism, which eventually results in the death and lysis of the host cell. Shut off of the host cell protein synthesis involves the virion host shutoff (vhs) protein, a ribonuclease that targets to polyribosomes and degrades host cell mRNA (Fig. 3, step 3) and provides an opportunity for translation of host mRNAs. Shut off of host transcription and of host RNA splicing also reduces host gene expression.

Epigenetic Regulation

HSV virion DNA is not associated with histones, but when the viral DNA enters the cell nucleus, host cell mechanisms rapidly load histones with heterochromatic post-translational modifications on the viral DNA so as to silence it. Virion protein 16 (VP16) from the tegument is released into the cytoplasm and localizes into the infected cell nucleus where it organizes a complex of host cell proteins that remove the heterochromatin marks and reduce the histone loading on the viral DNA, so that transcription factors and RNA polymerase II can have access to the viral DNA for its transcription. The IE ICP0 protein then acts to allow E and L gene expression. ICP0 is an E3 ubiquitin ligase that promotes the degradation of a number of host restriction factor proteins that increase heterochromatin on HSV DNA, including PML, IFI16, and ATRX. This leads to euchromatin across the HSV genome, allowing broad transcription of the genome.

Host Factors

Like all viruses, HSV uses numerous host proteins and structures for its replication. Human cells have also evolved numerous mechanisms to restrict replication of HSV. First, the cells detect foreign viral macromolecules, and activate mechanisms by constitutively expressed host proteins that block the activity of the viral molecules, a process called intrinsic resistance. One of the first mechanisms of resistance is the rapid loading of heterochromatin on the incoming viral genome, as described above. Alternatively, recognition of HSV DNA, altered host RNAs, or viral proteins can induce innate responses which result in expression of host proteins that reduce viral replication in the infected cell and surrounding cells. These responses may involve induction of cytokines such as interferons and interleukins. Type 1 interferons such as interferon α and interferon β are produced in infected cells and bind to receptors on that cell and surrounding cells to induce the expression of multiple antiviral genes collectively called interferon-stimulated genes (ISGs). ISGs encode protein products that block or reduce viral gene expression or replication. Interleukins induced by viral infection may induce antiviral mechanisms or recruit immune cells to the sites of viral infection and that reduce viral replication.

HSV has evolved a number of mechanisms to fight back against intrinsic resistance and innate immunity mechanisms. As described above, ICP0 promotes the degradation of host epigenetic restriction factors. ICP0 also blocks certain innate signaling pathways. In addition, the HSV-1 ICP34.5 protein blocks type 1 interferon signaling so the virus is less sensitive to type 1 interferons. The HSV-1 US3 protein kinase also blocks interferon signaling. Other examples can be found in the cited reviews.

Latent Infection

HSV latent infection of sensory neurons involves the binding of the virion to the termini of the neuronal axons and entry, likely using the same entry molecules as for lytic infection described above, into the axon. The capsid moves along the axon by retrograde transport to the neuronal cell body, where the viral genome is released into the neuronal nucleus. The genome circularizes and is loaded slowly with histones due to the small pool of free histones in the resting neuron; nevertheless, lytic gene transcription is limited due to the lack of localization of VP16 to the neuronal nucleus and the cytoplasmic localization of at least one of the host proteins that forms a complex with VP16 to activate IE gene expression. The major viral gene that is transcribed is the gene encoding the latency-associated transcript (LAT), which is a long (greater than 10 kb) non-coding RNA primary transcript. LAT is processed by splicing to yield a stable 2 kb circular intron, and several microRNAs (miRNAs). LAT expression acts to promote the survival of the infected neuron by increasing heterochromatin on the viral genome and reducing viral lytic gene expression and inhibiting apoptosis. LAT increases the levels of the H3K9me3 (histone H3 lysine 3 residue trimethylated) facultative heterochromatin marker, possibly by

recruiting the Polycomb repressive complex 2 histone methyltransferase. Facultative heterochromatin seems ideal for latent HSV chromatin because it is silencing, but it would constitute a form of chromatin that is poised for reactivation.

During maintenance of latent infection, there is minimal but detectable expression of HSV lytic genes. Because the neuron is a resting cell, the viral DNA genome can be maintained stably without replicating or being tethered to host chromosomes. Some have argued that CD8⁺ T cells surrounding the latently infected neuron maintain latent infection, but an alternative explanation is that they are targeting reactivating neurons. In any event, neuronal damage, stress, and/or activation lead to kinase signaling pathways believed to phosphorylate histones in viral chromatin to allow generalized transcription of the latent genome to provide enough VP16 to trigger the lytic transcriptional cascade. This allows at least a limited amount of viral gene expression to form capsids, and capsids or virions move along the axon by anterograde transport to release reactivated at the axonal termini to cause a recurrent infection. It has been debated as to whether the reactivating neuron survives or not, but neuronal survival is likely inversely proportional to the level of reactivated gene expression and not an all-or-none effect.

Epidemiology

HSV infection is transmitted by direct contact with an infected person's lesions, mucosal surfaces, or genital or oral secretions. The epidemiology of infection is best defined by the seroprevalence of HSV-1 and HSV-2. HSV infections remain common despite a recent steady decrease in prevalence (Fig. 4). The seroprevalence of HSV-1 and HSV-2 increases linearly with age and is higher in females. Primary HSV-1 infections usually occur in the young child and are most often asymptomatic. During the period of 1999–2002, HSV-1 seroprevalence in U.S.-born children ages 6–13 years was 31%, progressively increasing with age. In the most recent National Health and Nutrition Examination Survey (NHANES) of 2015–2016, the seroprevalence in people age 14–19 years was 27%, consistent with overall trends of decreasing prevalence of HSV-1 in early childhood over the last two decades. By adulthood, about half of the U.S. population (48%) has experienced HSV-1 infection. HSV-1 prevalence differs by race and ethnicity, with prevalence highest in the Mexican-American population and lowest in non-Hispanic whites, a finding that remains true despite a steady decline in overall prevalence in the U.S. The HSV-1 contribution to genital herpetic disease has increased over the past two decades. The percentage of people who randomly tested positive for HSV-1 only and had a diagnosis of genital herpes increased to 1.8% in NHANES survey 1999–2004 when compared to 0.4% in the NHANES survey 1988–1994. A retrospective evaluation of college students with newly diagnosed genital infection from 1993 to 2001 showed a striking increase of HSV-1 as a cause of symptomatic genital herpes from 30.9% in 1993 to 77.6% in 2001.

Fig. 4 Trends in age-adjusted prevalence of herpes simplex 1 among persons aged 14–49, for the total population and by race and Hispanic origin: United States, 1999–2000 through 2015–2016. ¹Significant decreasing linear trend over time, $p < 0.05$. **NOTES:** Age adjusted by the direct method to the 2000 U.S. Census population, using age groups 14–19, 20–29, 30–39, and 40–49 years. Total population includes all race and Hispanic-origin groups including those not shown separately. Data for the Asian subpopulation are only available since 2011, so this subpopulation is not shown separately, but included in the total population. Access data table at https://www.cdc.gov/nchs/data/databriefs/db304_table.pdf#2. Source: NCHS, National Health and Nutrition Examination Survey, 1999–2016.

Geographic location, socioeconomic status, and age influence the occurrence of HSV infection, regardless of the mode of assessment. The global estimates of the incidence and prevalence of HSV-1 infections vary by region, being around 67%, and highest in African, Southeast Asian and Western Pacific countries. The prevalence of HSV-1 is higher and occurs earlier in childhood outside of Europe and the Americas, with estimates reaching 90% in Africa by 10 years of age. As noted, most of these infections are asymptomatic.

The annual global incidence of HSV-1 infections is estimated to be 2% in 2012. The contribution of HSV-1 to the incidence of genital infections is less clearly defined in the developing world because prospective studies are lacking. Estimates of HSV-1 genital infections vary by region and are also impacted by both cultural sexual practices and the prevalence of childhood HSV-1 infections. In Africa, for example, the prevalence of genital HSV-1 is estimated to be 0%–0.1% (early childhood HSV-1 prevalence overall of 90%) compared to Eastern Mediterranean region with a 2%–3% prevalence of genital HSV-1 (early childhood HSV-1 prevalence close to 70%).

Acquisition of HSV-2 usually occurs in association with onset of sexual activity and directly correlates with the number of lifetime sexual partners. Overall, seroprevalence of HSV-2 in the U.S. decreased in recent years after a significant increase in the mid-1990s. The most recent studies showed total prevalence of 12% during 2015–2016, which represents a decrease from 17% during 1999–2004. HSV-2 remains more common among women when compared to men and non-Hispanic blacks compared to other race and ethnic groups. HSV-2 prevalence is also affected by factors such as age (linear increase with age), poverty (higher in people below poverty line), social status (higher in those who are divorced, separated or widowed), and number of lifetime sexual partners (3.8% in people who reported one partner compared to 39.9% in people reporting ≥ 50 sexual partners lifetime). Previous studies had indicated that men who have sex with men (MSM) have an increased prevalence of HSV-2. More recently, the NHANES 2001–2006 study did not detect a difference in HSV-2 prevalence overall between homosexual, bisexual or heterosexual men; however, there was a slightly increased prevalence of HSV-2 in homosexual individuals with HIV infection compared to heterosexual men. Worldwide estimates of HSV-2 infection in 2012 indicated an overall prevalence of 11.3%. Estimates vary significantly by gender and geographic area. Prevalence in females is higher, compared to males (14.8% versus 8%) and was highest in Africa with a prevalence of 31.5%. The estimated incidence of HSV-2 infections also differs by gender and geographic areas, being typically higher in the younger age groups. A decline of incidence with age was observed in areas with higher prevalence, which could be attributed to age-related behavioral changes or decrease in susceptible people at older ages. In general, women acquire HSV-2 infection more frequently than do men, irrespective of the number of partners.

For pregnant women, approximately 1% will excrete virus at the time of delivery. Nevertheless, the incidence of neonatal HSV infection is only approximately 1 in 1500 live born infants in the U.S. The incidence of neonatal HSV infection is affected by multiple factors, the most important of which is the maternal infection status. Pregnant women who contract genital HSV for the first time during the third trimester have the highest risk for transmitting infection to the fetus, as 57% of those neonates develop neonatal HSV infection. The rate of exposed neonates developing the disease decreases to 25% when pregnant women contract a first genital HSV infection but have a prior history of HSV infection of the other species. The risk drops significantly to 2% at most, for neonates born to women with established recurrent genital HSV of either species. The decrease in neonatal HSV infection with documented recurrent genital HSV infection is likely due to the protective transplacental antibodies. Cesarean delivery reduces the risk of neonatal HSV infection by avoiding exposure to viral shedding in maternal vaginal secretions. Other risk factors for neonatal HSV infection, particularly in women with established genital infection, include application of a fetal scalp electrode, virus species (higher risk with HSV-1 versus HSV-2), and duration of membrane rupture. Global estimates of annual neonatal HSV incidence is about 14,257 neonates from 2010 to 2015 with HSV-2 being responsible for about two thirds of the total number. The global rate of neonatal HSV is estimated to be around 10.3 per 100,000 live births. The estimated global annual incidence of neonatal HSV disease is significantly lower than that of the U.S. The reason behind this significant difference is not clear yet, and further studies are needed to identify potential explanations. Both HSV-1 and HSV-2 seem to contribute almost equally to neonatal HSV diseases in the U.S. This is not the case in other areas of the world where childhood HSV-2 prevalence is significantly higher, as in Africa where almost all neonatal HSV cases are thought to be due to HSV-2.

Nosocomial HSV infection has been documented both in newborn nurseries as well as in intensive care units.

Clinical Features

Mucocutaneous Infections

Gingivostomatitis

Mucocutaneous infections are the most common clinical manifestations of HSV-1 and HSV-2. Gingivostomatitis is usually caused by HSV-1 and occurs most frequently in children under five years of age. Clinical disease is characterized by fever, sore throat, pharyngeal edema, and erythema, followed by the development of vesicular or ulcerative lesions of the oral or pharyngeal mucosa. Skin lesions are usually grouped vesicles on an erythematous base. Mucous membrane vesicles usually rupture, resulting in a painful ulcerative lesion on an erythematous base, which is prone to bleeding. In children, clinical fussiness occurs and is associated with decreased oral intake that may lead to dehydration. Auto-inoculation of HSV from oral lesions to fingers results in herpetic whitlow, not uncommon in the pediatric population.

Another manifestation of mucocutaneous HSV is eczema herpeticum, which develops in patients with skin eczema and may not be limited to one area, but rather involves multiple patches of the skin affected by poorly controlled eczema. Mucocutaneous HSV lesions usually heal without leaving a scar at the site of infection. Recurrent HSV-1 infections of the oropharynx frequently manifest as herpes simplex labialis (cold sores) and appear on the vermilion border of the lip. Intraoral lesions, as a manifestation of recurrent disease, are uncommon in the normal host but do occur frequently in the immunocompromised host.

Genital herpes

HSV-2 was the major cause of genital herpes in the past, but recent studies indicate that probably over half of new genital herpes cases are caused by HSV-1. Primary infection in women usually involves the vulva, vagina, and cervix. In men, initial infection is most often associated with lesions on the glans penis, prepuce, or penile shaft. In individuals of either sex, primary disease is associated with fever, malaise, anorexia, and bilateral inguinal adenopathy. Women frequently have dysuria and urinary retention due to urethral involvement. As many as 10% of individuals will develop an aseptic meningitis with primary infection. Aseptic meningitis, often presenting as recurrent disease known as Mollaret's meningitis, usually presents with fever, photophobia, headache, and neck stiffness. It is more likely to happen in women with genital HSV-2 infections. Sacral radiculomyelitis may occur in both men and women, resulting in neuralgias, urinary retention, or obstipation. The complete healing of primary infection may take several weeks. The first episode of genital infection is less severe in individuals who have had previous HSV infections at other sites, such as herpes simplex labialis. Primary genital HSV is more likely to be asymptomatic regardless of viral species. Recurrent lesions with viral shedding could also be asymptomatic, explaining the high incidence of new infections.

Recurrent genital infections in either men or women can be particularly distressing. The frequency of recurrence varies significantly from one individual to another. For those with HSV-2 infection, approximately one-third of individuals with genital herpes have virtually no recurrences, one-third have approximately three recurrences per year, and another third have more than three per year, while those individuals with HSV-1 infection are much less likely to suffer recurrences. By applying polymerase chain reaction assays to genital swabs from women with a history of recurrent genital herpes, viral DNA can be detected in the absence of culture proof of infection. Further, HSV DNA can be detected in over 20% of days in women. This finding suggests the chronicity of genital herpes in some women, as opposed to a recurrent infection.

Epidemiological studies have also shown that HSV-2 infection increases the risk of human immunodeficiency virus (HIV) acquisition and transmission. It is postulated that inflammation in the genital tract caused by HSV-2 infection leads to increased activated CD4⁺ T cells that are the host cells for HIV infection, and this would lead to increased acquisition and transmission of HIV. This is of importance because genital herpes is potentially a major risk factor for HIV infection.

Herpetic keratitis

HSV keratitis is usually caused by HSV-1, either primary or recurrent and is accompanied by conjunctivitis in many cases. It is considered among the most common infectious causes of blindness in the U.S. The characteristic lesions of HSV keratoconjunctivitis are dendritic ulcers best detected by fluorescein staining. Deep stromal involvement has also been reported and may result in visual impairment. Acute necrotizing retinitis is a rare complication that leads to painless loss of vision. Chorioretinitis is another rare HSV ophthalmic complication that could develop in neonates or immunocompromised patients with HSV infections.

Other skin manifestations

HSV infections can manifest at any skin site. Common among health-care workers are lesions on abraded skin of the fingers, known as herpetic whitlows. Similarly, because of physical contact, wrestlers may develop disseminated cutaneous lesions known as herpes gladiatorum. HSV infections have also been recognized as a trigger for erythema multiforme.

Neonatal Herpes Simplex Virus Infection

The incidence of neonatal HSV is estimated to be 1 in 1500 live births in the U.S. Most (85%) affected neonates acquire HSV from exposure to infected secretions during birth (intrapartum acquisition), a small number (10%) acquire the virus postnatally, and rarely (~5%) the virus is acquired *in utero*, resulting in congenital HSV infection. Manifestations of neonatal HSV infection can be divided into three categories: (a) skin, eye, and mouth disease (SEM) (45% of all neonatal HSV cases); (b) CNS disease (30%); and (c) disseminated infection (25%). Most HSV infections during the neonatal period present with fever, lethargy, poor feeding, skin lesions, or seizures. In SEM, as the name implies, skin, eye, and mouth disease consists of cutaneous lesions (in >80%) and does not involve other organ systems. Involvement of the central nervous system may occur with encephalitis or disseminated infection and generally results in a diffuse encephalitis and results in seizures and lethargy. Cerebrospinal fluid analysis characteristically reveals an elevated protein and a mononuclear pleocytosis. Disseminated infection involves multiple organ systems and can produce disseminated intravascular coagulation, hemorrhagic pneumonitis, encephalitis, hepatitis, and cutaneous lesions. Diagnosis can be particularly difficult in the absence of skin lesions. The mortality rate for each disease classification varies from zero for skin, eye, and mouth disease to 15% for encephalitis and 60% or higher for neonates with disseminated infection in the absence of therapy. In addition to the high mortality associated with these infections, morbidity is significant in that children with encephalitis or disseminated disease develop normally in only approximately 40% of cases, even with the administration of appropriate antiviral therapy. Congenital HSV (acquired *in utero*, about 5% of neonatal HSV cases) manifests as a triad of skin

involvement (lesions, scarring and change of pigmentation), CNS involvement (calcifications and microcephaly), and ophthalmologic involvement (chorioretinitis and optic atrophy). Affected neonates are usually very ill.

Herpes Simplex Encephalitis

HSV encephalitis is characterized by hemorrhagic necrosis of the inferomedial portion of the temporal lobe. Disease begins unilaterally, then spreads to the contralateral temporal lobe. It is the most common cause of focal, sporadic encephalitis in the U.S. today and occurs in approximately 1 in 250,000 to 500,000 individuals. Most cases are caused by HSV-1. The actual pathogenesis of herpes simplex encephalitis is unknown, although it has been speculated that primary or recurrent virus can reach the temporal lobe by ascending neural pathways, such as the trigeminal tracts or the olfactory nerves.

Clinical manifestations of herpes simplex encephalitis include headache, fever, altered consciousness, and abnormalities of speech and behavior. Focal seizures may also occur. The cerebrospinal fluid formulae for these patients is variable, but usually consists of a pleocytosis of monocytes. The protein concentration is characteristically elevated, and glucose is usually normal. Red blood cells may or may not be present. Historically, a definitive diagnosis could be achieved only by brain biopsy, because other pathogens may produce a clinically similar illness. However, the application of polymerase chain reaction (PCR) for detection of virus DNA has replaced brain biopsy as the standard for diagnosis. The mortality and morbidity are high, even when appropriate antiviral therapy is administered. At present, the mortality rate is approximately 14%–19% even with appropriate intravenous (IV) acyclovir (mortality exceeds 70% without effective therapy). Approximately 50% of survivors will have significant neurologic sequelae.

Herpes Simplex Virus Infections in the Immunocompromised Host

HSV infections in the immunocompromised host are clinically more severe, may be progressive, and require more time for healing. Manifestations of HSV infections in this patient population include pneumonitis, esophagitis, hepatitis, colitis, and disseminated cutaneous disease. Individuals suffering from human immunodeficiency virus infection may have extensive perineal or orofacial ulcerations. HSV infections are also noted to be of increased severity in individuals who are burned.

Pathogenesis

Acquisition of HSV infections requires intimate contact between a person who is shedding virus and a susceptible host. After inoculation of HSV onto the skin or mucous membrane and an incubation period of 4–6 days, clinical disease may occur or, as is more common, the infection will be asymptomatic. HSV replicates in epithelial cells and fibroblasts. As replication continues, cell lysis and local inflammation ensue, resulting in characteristic vesicles on an erythematous base. Regional lymphatics and lymph nodes become involved; therefore, viremia and visceral dissemination may develop, depending upon the immunologic competence of the host. In all hosts, the virus generally ascends peripheral sensory nerves and reaches sensory ganglia. Replication of HSV within neural tissue is followed by anterograde axonal spread of the virus back to other mucosal and skin surfaces via the peripheral sensory nerves. Virus replicates further in the epithelial cells, reproducing the lesions of the initial infection, until infection is contained through both systemic and mucosal immune responses.

The initial host response to HSV infection is derived mainly from the innate immune system including natural killer (NK) cells, neutrophils, B cells, and T cells, as well as production of cytokines and recruitment of adaptive and humoral immune response. HSV-specific antibodies and, subsequently, CD8 and CD4 lymphocytes develop with time. Prevention of latent infection is not possible; thus, latency is inevitable. The production of HSV-specific neutralizing antibodies contributes to the control of infection and is also used in laboratory testing to detect the viral infection.

Latency is established when HSV reaches the dorsal root ganglia after retrograde transmission via sensory nerve pathways. The virus does not actively replicate during latency. Reactivation of latent infection results in one of two outcomes: asymptomatic viral shedding (more likely) or reactivation that results in disease with a clinical presentation similar to, but usually milder than, the original symptomatic infection. Reactivation of a latent infection may be symptomatic despite the asymptomatic nature of the original primary infection.

Rarely, HSV can infect the central nervous system and cause encephalitis. The focality and temporal lobe affinity suggest direct extension of virus along neural tracts. Encephalitis caused by HSV is characterized by necrosis of the inferior medial portion of the temporal lobe, initially unilaterally and then contralaterally. This necrotic process accounts for the high morbidity and mortality of infection. Specific genetic mutations in the innate immune system make affected hosts susceptible to severe or recurrent disease. For example, toll-like receptor 3 (TLR-3) mutations have been reported to increase the risk for HSE in pediatric and young adults from the same family.

Infection of the neonate is usually the consequence of direct contact with infected maternal genital secretions, accounting for approximately 85% of cases of neonatal herpes. The remaining 15% are caused by *in utero* infection (5%), secondary to viremia, or postnatal acquisition whereby the baby comes in contact with infectious virus in the environment.

Diagnosis

The diagnosis of HSV infections is predicated on clinical evaluation of mucocutaneous manifestations. However, confirmation of the diagnosis requires isolation of HSV in appropriate cell culture systems or the detection of viral gene products or, alternatively,

the detection of viral DNA by polymerase chain reaction (PCR). HSV grows readily in tissue culture, producing cytopathic effects within a few days in a wide variety of mammalian cell lines. Routine testing to distinguish HSV-1 from HSV-2 in the isolate is important for genital isolates because HSV-1 is much less likely to recur.

PCR is an important method for diagnosing HSV infections, particularly those involving the central nervous system. The detection of HSV DNA by PCR in the CSF has replaced brain biopsy as a method of diagnosis of central nervous system infections.

Serologic assays that distinguish HSV-1-versus HSV-2-specific antibodies are commercially available. The utilization of immunoblot detection of specific glycoproteins that distinguish HSV-1 from HSV-2, namely, glycoprotein G-1 (gG-1) and gG-2, are available for determining prior exposure to HSV-1 and HSV-2 infections. Serologic testing is also used for population-based studies to identify the prevalence of the disease.

Historically, Tzanck smears have been used to diagnose HSV infections. Tzanck smears are not sensitive enough for routine diagnostic purposes. However, immunofluorescent staining of cell trap preparations from lesions is both sensitive and specific for the diagnosis for HSV infections.

Treatment

Infections due to HSV are amenable to treatment. Acyclovir and its pro-drug (valacyclovir) as well as famciclovir (pro-drug of penciclovir) are the mainstays of treatment. Acyclovir is mono-phosphorylated by the viral TK, and di- and tri-phosphorylates are added by cellular enzymes. Acyclovir tri-phosphate is recognized specifically by the viral DNA polymerase and incorporated into the growing viral DNA chain. Acyclovir causes chain termination and inhibits viral DNA synthesis. Valacyclovir is a pro-drug that metabolizes to acyclovir and results in good serum levels, similar to levels achieved with IV acyclovir. Famciclovir undergoes metabolic conversion to penciclovir which is active against HSV. Dose, route, and duration of therapy vary considerably depending on the site of infection and status of the patient. The use of high-dose acyclovir and addition of suppressive therapy has improved outcomes significantly in neonatal HSV infections.

Primary mucocutaneous infections in the immunocompetent host are treated with oral acyclovir or valacyclovir for 7–10 days; famciclovir can also be used. Valacyclovir is FDA-approved in the pediatric population 12 years of age or older. Recurrent orolabial HSV infection can be treated with any of these three drugs. Suppressive therapy may be considered for patients with very frequent recurrent lesions. Patients with genital HSV infection can be treated with acyclovir, valacyclovir, or famciclovir. IV acyclovir should be considered in the initial phase of treating severe orolabial disease leading to decreased oral intake in a pediatric patient or in an adult with genital herpes associated with aseptic meningitis. Treatment of genital herpes in the HIV-infected patient may be followed by long term suppressive therapy with acyclovir, valacyclovir or famciclovir.

Topical therapy with one of several antiviral ophthalmic preparations is appropriate for HSV keratoconjunctivitis. However, the treatment of choice is Viroptic or trifluorothymidine. Secondary choices include vidarabine ophthalmic or topical idoxuridine. Consultation with an ophthalmologist for confirmation of the diagnosis and management of HSV ocular disease is indicated.

Neonatal HSV infection should always be treated with IV acyclovir. The duration of treatment varies: CNS and disseminated diseases are treated for 21 days and SEM only 14 days. All forms of neonatal HSV should be followed by a minimum of 6 months of suppressive therapy with oral acyclovir. Neonatal disease involving the eyes should also be treated with topical ophthalmic drugs (trifluridine or topical ganciclovir), and an ophthalmologist consulted.

IV acyclovir is the mainstay of HSV encephalitis during adulthood. Encephalitis patients require longer treatment duration of 14–21 days as compared to 7–10 days for aseptic meningitis. Acyclovir resistance can develop. Resistance is usually related to viral TK mutations. The treatment of choice for infections caused by acyclovir-resistant strains is foscarnet. Consultation with specialists is recommended when resistance is known or suspected.

Prevention

At the present, there is no licensed vaccine for the prevention for HSV infections. Vaccines in clinical testing include DNA vaccines, replication-defective viruses, and protein subunits with new adjuvants. Consequently, prevention of HSV infections resides in the most part on knowledge of the mechanisms of transmission, including person to person as well as in the hospital environment. Individuals with known recurrent HSV infections should be counseled on the possibility of transmission of infection while lesions are present. The use of condoms for individuals with recurrent genital herpes is encouraged in that detection of HSV DNA by PCR can occur even in the absence of lesions. Similarly, for individuals who have recurrent herpes labialis, kissing should be discouraged.

There is a risk of nosocomial transmission of HSV within the hospital environment. Because many individuals shed HSV in the absence of clinical symptoms, it is impossible to exclude all workers from the hospital environment who could transmit infection. Thus, many authorities simply recommend strict hand washing and covering of lesions, should they exist.

Finally, no data exist on the prevention of neonatal HSV infection. It has been theorized that anticipatory administration of acyclovir to babies delivered through an infected birth canal may prove of value, particularly for women who have first episode genital herpetic infection. However, no data exist to substantiate this hypothesis. Because over 1% of all women at delivery excrete HSV and the rate of neonatal HSV infection is only 1 in 1500 live born infants as noted earlier, the routine administration of acyclovir to all children born to HSV-positive women is not reasonable. Alternative approaches, namely administration of acyclovir to known HSV-2-infected women is gaining acceptance.

This is a reproduction of F. Fenner, History of Virology: Vertebrate Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00424-6](https://doi.org/10.1016/B978-012374410-4.00424-6).

Introduction

As in other branches of experimental science, the development of our knowledge of viruses has depended on the techniques available. Initially, viruses were studied by pathologists interested in the causes of the infectious diseases of man and his domesticated animals and plants and these concerns remain the main force advancing the subject. The idea that viruses might be used to probe fundamental problems of biology arose in the early 1940s, with the development of the knowledge of bacterial viruses. These studies helped establish the new field of molecular virology in the period 1950–70, and this has revolutionized the study of viruses and led to an explosion of knowledge about them.

The Word Virus

Since antiquity the term virus had been synonymous with poison, but during the late nineteenth century it became a synonym for microbe (Pasteur's word for an infectious agent). It did not acquire its present connotation until the 1890s, after the bacterial or fungal causes of many infectious diseases had been discovered, using the agar plate, effective staining methods, and efficient microscopes. It then became apparent that there were a number of infectious diseases of animals and plants from which no bacterium or fungus could be isolated or visualized with the microscope. After the introduction in 1884 of the Chamberland filter, which held back bacteria, Loeffler and Frosch demonstrated that the cause of foot-and-mouth disease was a filterable (or ultramicroscopic) virus. The first compendium of all then known viruses was edited by T. M. Rivers of the Rockefeller Institute and published in 1928. Entitled *Filterable Viruses*, this emphasized that viruses required living cells for their multiplication. In the 1930s chemical studies of the particles of tobacco mosaic virus and of bacteriophages showed that they differed from all cells in that at their simplest they consisted of protein and nucleic acid, which was either DNA or RNA. Gradually, the adjectives filterable and ultramicroscopic were dropped and the word viruses developed its present connotation.

Early Investigations

Foot-and-Mouth Disease Virus

In 1898 F. J. Loeffler and P. Frosch described the filterability of an animal virus for the first time, noting that “the filtered material contained a dissolved poison of extraordinary power or that the as yet undiscovered agents of an infectious disease were so small that they were able to pass through the pores of a filter definitely capable of retaining the smallest known bacteria.” Although the causative agent of foot-and-mouth disease passed through a Chamberland-type filter, it did not go through a Kitasato filter which had a finer grain. This led to the conclusion that the causative virus, which was multiplying in the host, was a corpuscular particle. Loeffler and Frosch gave filtration a new emphasis by focussing attention on what passed through the filter rather than what was retained and established an experimental methodology which was widely adopted in the early twentieth century in research on viral diseases.

Yellow Fever Virus

Following the acceptance of the notion of filterable infectious agents, pathologists investigated diseases from which no bacteria could be isolated and several were soon shown to be caused by viruses. One of the most fruitful investigations, in terms of new concepts, was the work of the United States Army Yellow Fever Commission headed by Walter Reed in 1900–01. Using human volunteers, they demonstrated that yellow fever was caused by a filterable virus which was transmitted by mosquitoes and that the principal vector was *Aedes aegypti*. They also showed that infected persons were infectious for mosquitoes only during the first few days of the disease and that mosquitoes were not infectious until 7–10 days after imbibing infectious blood, thus defining the extrinsic incubation period and establishing essentially all of the basic principles of the epidemiology of what came to be called arboviruses (arthropod-borne viruses).

Physical Studies of Viruses

Further advances in understanding the nature of viruses depended on physical and chemical studies. As early as 1907 H. Bechhold in Germany developed filters of graded permeabilities and a method of determining their pore size. Subsequently, W. J. Elford, in London, used such membranes for determining the size of animal virus particles with remarkable accuracy.

In Germany, on the eve of World War II, H. Ruska and his colleagues had produced electron microscopic photographs of the particles of tobacco mosaic virus, bacteriophages, and poxviruses. Technical improvements in instrumentation after the war, and the introduction of negative staining for studying the structure of viruses by Cambridge scientists H. E. Huxley in 1957 and S. Brenner and R. W. Horne in 1959 resulted in photographs of the particles of virtually every known kind of virus. These demonstrated the variety of their size, shape, and structure, and the presence of common features such as the icosahedral symmetry of many viruses of animals.

Following a perceptive paper on the structure of small virus particles by F. H. C. Crick and J. D. Watson in 1956, in 1962 D. L. D. Caspar of Boston and A. Klug of Cambridge, England, produced a general theory of the structure of regular virus particles of helical and icosahedral symmetry. Structure of the virus particle became one of the three major criteria in the system of classification of viruses that was introduced in 1966.

The Chemical Composition of Viruses

If the ultramicroscopic particles found in virus-infected hosts were the pathogens, what did these particles consist of? Following observations on plant and bacterial viruses in 1935, in 1940 C. L. Hoagland and his colleagues at the Rockefeller Institute found that vaccinia virus particles contained DNA but no RNA. Thus evidence was accumulating that viruses differed from bacteria not only in size and their inability to grow in lifeless media, but in that they contained only one kind of nucleic acid, which could be either DNA or RNA.

The development of restriction-endonuclease digestion of DNA, based on studies of phage restriction by W. Arber (Nobel Prize, 1978) of Basel in the 1960s, and then elaborated by biochemist H. O. Smith of Baltimore in 1970, has simplified the mapping of the genomes of DNA viruses, a study initiated by D. Nathans (Nobel Prize, 1978), also of Baltimore, using Simian virus 40. The development of the polymerase chain reaction in 1985 by K. B. Mullis (Nobel Prize, 1993) revolutionized sequencing methods for both DNA and RNA, leading to the availability of the complete genomic sequences of most viruses and the ability to make diagnoses using minute amounts of material.

Investigations of bacterial viruses were motivated by scientific curiosity, but animal virology was developed by pathologists studying the large number of diseases of humans and livestock caused by viruses, and it has retained this practical bias. Over the first two decades of the twentieth century, testing of filtrates of material from a number of infected humans and animals confirmed that they were caused by viruses. Among the most important was the demonstration in 1911 by P. Rous (Nobel Prize, 1966), at the Rockefeller Institute, that a sarcoma of fowls could be transmitted by a bacteria-free filtrate.

The Cultivation of Animal Viruses

The first systematic use of small animals for virus research was Pasteur's use of rabbits, which he inoculated intracerebrally with rabies virus in 1881. It was not until 1930 that mice were used for virus research, with intracerebral inoculations of rabies and yellow fever viruses. By using graded dilutions and large numbers of mice, quantitative animal virology had begun. The next important step, initiated by E. W. Goodpasture in 1931–32, was the use of chick embryos for growing poxviruses. This was followed a few years later by the demonstration by F. M. Burnet that many viruses could be titrated by counting the pocks that they produced on the chorioallantoic membrane, whereas others grew well in the allantoic and/or amniotic cavities of developing chick embryos.

Tissue cultures had first been used for cultivating vaccinia virus in 1928, but it was the discovery by J. F. Enders, T. H. Weller, and F. C. Robbins of Harvard University (Nobel Prize, 1954) in 1949 that poliovirus would grow in non-neural cells that gave a tremendous stimulus to the use of cultured cells in virology. Over the next few years their use led to the cultivation of medically important viruses such as those causing measles (by J. F. Enders and T. C. Peebles in 1954) and rubella (by T. H. Weller and F. C. Neva in 1962). Even more dramatic was the isolation of a wide variety of new viruses, belonging to many different families. Also the different cytopathic effects produced by different viruses in monolayer cell cultures were found to be diagnostic.

The next great advance, which greatly increased the accuracy of quantitative animal virology, occurred in 1952, when the plaque assay method for counting phages was adapted to animal virology by R. Dulbecco (Nobel Prize, 1975), using a monolayer of chick embryo cells in a petridish. In 1958 H. Temin and H. Rubin applied Dulbecco's method to Rous sarcoma virus, initiating quantitative studies of tumor viruses. Biochemical studies of animal virus replication were simplified by using continuous cell lines and by growing the cells in suspension.

Biochemistry

During the 1950s virus particles were thought to be 'inert' packages of nucleic acid and proteins, although in 1942 G. K. Hirst of the Rockefeller Institute had shown that particles of influenza virus contained an enzyme, later identified by A. Gottschalk of Melbourne as a neuraminidase.

Further advances in viral biochemistry depended on methods of purification of virus particles, especially the technique of density gradient centrifugation. In 1967 J. Kates and B. R. McAuslan demonstrated the presence of a DNA-dependent RNA polymerase in purified vaccinia virus virions, a discovery that was followed the next year by the demonstration of a double-stranded (ds) RNA-dependent RNA polymerase in reovirus virions and then of single-stranded (ss) RNA-dependent RNA polymerases in virions of paramyxoviruses and rhabdoviruses. In 1970 came the revolutionary discovery by D. Baltimore of Boston (Nobel Prize, 1975) and H. Temin of Wisconsin (Nobel Prize, 1975), independently, of the RNA-dependent DNA polymerase, or reverse transcriptase, of Rous sarcoma virus. Many other kinds of enzymes were later identified in the larger viruses; for example, no less than 16 enzymes have now been identified in vaccinia virus virions.

Just as investigations with bacterial viruses were of critical importance in the development of molecular biology, studies with animal viruses have led to the discovery of several processes that have proved to be important in the molecular biology of eukaryotic cells, although many of these discoveries are too recent for serious historical appraisal. Thus, in 1968 M. Jacobson and D. Baltimore of Boston showed that the genomic RNA of poliovirus was translated as a very large protein, which was then cleaved by a protease that was subsequently found in the viral replicase gene. RNA splicing was discovered in 1977, independently by P. A. Sharp (Nobel Prize, 1993) and L. T. Chow and their respective colleagues during studies of adenovirus replication. Work with the same virus by Rekosh and colleagues in London in 1977 resulted in the definition of viral and cell factors for initiation of new DNA strands using a novel protein priming mechanism. Capping of mRNA by m⁷G and its role in translation was discovered in 1974, during work with reoviruses by A. J. Shatkin. Other processes first observed with animal viruses and now known to be important in eukaryotic cells were the existence of 3' poly A tracts on mRNAs, the pathway for synthesis of cell surface proteins, and the role of enhancer elements in transcription.

Analysis of viral nucleic acids progressed in parallel with that of the viral proteins. Animal viruses were found with genomes of ssRNA, either as a single molecule, two identical molecules (diploid retroviruses), or segmented; dsRNA; ssDNA, dsDNA, and partially dsDNA. The so-called unconventional viruses or prions of scrapie, kuru, and Creutzfeld-Jacob disease, which have been extensively investigated since 1957 by D. C. Gajdusek of the US National Institutes of Health (Nobel Prize, 1976) and S. B. Prusiner of the University of California at San Francisco (Nobel Prize, 1997), appear to be infectious proteins. Soon after the discovery that the isolated nucleic acid of tobacco mosaic virus was infectious (see below), it was shown that the genomic RNAs of viruses belonging to several families of animal viruses were infectious; namely those with single, positive-sense RNA molecules. Then in 1973 came the discovery of recombinant DNA by P. Berg of Stanford University and his colleagues, using the animal virus SV40 and bacteriophage λ .

Structure of the Virion

Using more sophisticated methods of electron microscopy, many animal virus virions have been shown to be isometric icosahedral structures, or roughly spherical protein complexes surrounded by a lipid-containing shell, the envelope, which contains a number of virus-coded glycoprotein spikes. X-ray crystallography of crystals of purified isometric viruses has revealed the molecular structure of their icosahedra; similar revealing detail has been obtained for the neuraminidase and hemagglutinin spikes of influenza virus.

Tumor Virology

After the discovery of Rous sarcoma virus in 1911, there was a long interval before the second virus to cause tumors, rabbit papilloma virus, was discovered by R. E. Shope in 1933. However, after that viruses were found to cause various neoplasms in mice, and in 1962 J. J. Trentin of Yale University showed that a human adenovirus would produce malignant tumors in hamsters. Since then, direct proof has been obtained that several DNA viruses (but not adenoviruses) and certain retroviruses can cause tumors in humans. Molecular biological studies have shown that oncogenicity is largely caused by proteins they produce that are encoded by viral oncogenes, a concept introduced by R. J. Huebner and G. Todaro of the US National Institutes of Health in 1969 and corrected, refined, and greatly expanded since the mid-1970s by J. M. Bishop, H. Varmus (Nobel Prize, 1989), and R. A. Weinberg of Boston.

Only one group of RNA viruses, the retroviruses, which replicate through an integrated DNA provirus, cause neoplasms, whereas viruses of five groups of DNA viruses are tumorigenic. Study of these oncogenic viruses has shed a great deal of light on the mechanisms of carcinogenesis. Oncogenic DNA viruses contain oncogenes as an essential part of their genome, which when integrated into the host cell DNA may promote cell transformation, whereas the oncogenes of retroviruses are derived from proto-oncogenes of the cell.

Impact on Immunology

Immunology arose as a branch of microbiology and several discoveries with animal viruses were important in the development of important concepts in immunology. It was the discovery in the 1930s by E. Traub in Tübingen of persistent infection of mice with

lymphocytic choriomeningitis virus that led to the development by F. M. Burnet (Nobel Prize, 1960) of the concept of immunological tolerance in 1949. It was work with the same virus that led to the discovery of MHC restriction by P. C. Doherty and R. Zinkernagel in Canberra (Nobel Prize, 1996) in 1974.

Vaccines and Disease Control

From the time of Pasteur's use of rabies vaccine in 1885, a major concern of medical and veterinary virologists has been the development of vaccines. Highlights in this process have been the development of the 17D strain of yellow fever virus by M. Theiler (Nobel Prize, 1951) of the Rockefeller Foundation laboratories in 1937, the introduction of influenza vaccine in 1942, based on Burnet's 1941 discovery that the virus would grow in the allantois, the licensing in 1954 of inactivated poliovaccine developed by J. Salk and in 1961 of the live poliovaccine introduced by A. B. Sabin, both based on the cultivation of the virus in 1949 by Enders, and development of the first genetically engineered human vaccine with the licensing of yeast-grown hepatitis B vaccine in 1986. Finally, 1977 saw the last case of natural smallpox in the world and thus the first example of the global eradication of a major human infectious disease, the result of a 10-year campaign conducted by the World Health Organization with a vaccine directly derived from Jenner's vaccine, first used in 1796.

Recognition of HIV-AIDS

In 1981 a new disease was described in the male homosexual populations of New York, San Francisco, and Los Angeles. It destroyed the immune system, and the disease was called the acquired immune deficiency syndrome (AIDS) and the causal virus, human immunodeficiency virus (HIV), a retrovirus, was first isolated by L. Montagnier, of the Pasteur Institute in Paris, in 1983. A sexually transmitted disease, it has now spread all over the world, with about 40 million cases worldwide, and without very expensive chemotherapy is almost always fatal. It is now clear that it arose from an inapparent but persistent infection of chimpanzees in Africa. In spite of enormous efforts over the past 20 years, it has so far been impossible to devise an effective vaccine.

Arthropod-Borne Viruses of Vertebrates

Arthropods, mainly insects and ticks, were early shown to be important as vectors of virus diseases of vertebrates (the arboviruses) and of plants. Sometimes, as in myxomatosis, carriage was found to be mechanical, but in most cases the virus was found to multiply in the vector as well as the vertebrate concerned. The development of methods of growing insect cells in culture by T. D. C. Grace in Canberra in 1962 opened the way for the molecular biological investigation of the replication of insect viruses and arboviruses in invertebrate cells.

Taxonomy and Nomenclature

After earlier tentative efforts with particular groups of viruses, viral nomenclature took off in 1948, with the production of a system of latinized nomenclature for all viruses by the plant virologist F. O. Holmes. This stimulated others, in particular C. H. Andrewes of London and A. Lwoff of Paris, to actions which resulted in the setting up of an International Committee on Nomenclature (later Taxonomy) of Viruses in 1966. Adopting the kind of viral nucleic acid, the strategy of replication, and the morphology of the virion as its primary criteria, this committee has now achieved acceptance of its decisions by the great majority of virologists. One interesting feature of its activities is that its rules avoid the controversies about priorities that plague taxonomists working with fungi, plants, and animals.

The Future

The future will see an explosive expansion of understanding and knowledge of viruses of vertebrates, with the application of techniques of genetic engineering, nucleic acid sequencing, the polymerase chain reaction, and the use of monoclonal antibodies. All these discoveries are addressed in the appropriate sections of this encyclopedia. Molecular biology, which was initially conceived during studies of bacterial viruses, is now being used to study all the viruses of vertebrates and the pathogenesis and epidemiology of animal viral diseases. The expansion in knowledge of these subjects in the next decade can be expected to exceed that of the previous century.

Nomenclature

AAV adeno-associated virus, in genus *Dependoparvovirus*
AGE acute gastroenteritis
ARTI acute respiratory tract infection
B19V human parvovirus B19, in *Erythroparvovirus*
BocaSR bocavirus-transcribed small RNA
BPV1 bovine parvovirus 1, in *Bocaparvovirus*
BuV bufavirus, in *Protoparvovirus*
CPV canine parvovirus, in *Protoparvovirus*
CSF cerebrospinal fluid
CuV cutavirus, in *Protoparvovirus*
CTCL cutaneous T-cell lymphoma
dsDNA double-stranded DNA
EIA enzyme immunoassay
HAE human airway epithelium
HAE-ALI human airway epithelium cultured at an air-liquid interface
HBoV human bocavirus, in *Bocaparvovirus*
HEK293 human embryonic kidney 293 cells
IgG immunoglobulin G
IgM immunoglobulin M
kDa kilo Dalton
LEH left-end hairpin (of the genome)
MVC minute virus of canines, in *Bocaparvovirus*

MVM minute virus of mice, in *Protoparvovirus*
NCR noncoding region (of genome)
NP1 nuclear phosphoprotein 1
NPS nasopharyngeal sample
NS1–4 non-structural protein 1–4
nt nucleotide
OAS original antigenic sin (an immunological phenomenon)
ORF open reading frame
(pA)d distal polyadenylation site
(pA)p proximal polyadenylation site
PCR polymerase chain reaction
PLA₂ phospholipase A₂
Pre-mRNA precursor mRNA
qPCR quantitative PCR
REH right-end hairpin (of genome)
RT-PCR reverse transcription PCR
ssDNA single-stranded DNA
TuV tusavirus, in *Protoparvovirus*
VP1–3 viral capsid proteins 1–3, with long common C-termini
VP1u a short unique N-terminus of VP1, which is not shared with VP2 or 3

Glossary

Cutaneous T-cell lymphoma (CTCL) A rare form of cancer affecting mature T cells in skin, forming skin lesions. CTCL is a class of non-Hodgkin lymphoma with unknown etiology, and is divided into several subtypes, including mycosis fungoides and Sézary syndrome.

HAE-ALI Human airway epithelium cultured at an air-liquid interface: Human bronchial/tracheal epithelial cells are cultured on microporous membrane inserts in wells. After 3–4 weeks at an air-liquid interface, cells are polarized into apical side that is exposed to the air and basolateral side that is dipped into liquid media.

IgG avidity The avidity, or binding force, of IgG to its antigen increases with the slowly maturing immune response after acute primary infection and can be measured by a protein-denaturing EIA disrupting the weak antigen-antibody bond in acute infection but not the stronger bond in past immunity.

Original antigenic sin (OAS) An immunological phenomenon (long-known from influenza and dengue virus infections) observed when a prior virus infection of an individual fully or partly hinders the induction of antibodies to the currently infecting related virus, and instead the original virus-specific IgG response is enhanced.

Introduction

Novel parvovirus sequences have been obtained after filtration, DNase treatment, and random PCR, followed by large-scale sequencing and bioinformatics. The first human bocavirus, HBoV1, was discovered in 2005 in airway samples of children with acute respiratory tract infection (ARTI). HBoV1 causes mild to life-threatening ARTI in young children worldwide. It is thus the second human-pathogenic parvovirus after parvovirus B19 (B19V). Three other closely related human bocaviruses, HBoV2, 3, and 4, have since been discovered in stool, but their association with acute gastroenteritis (AGE) is disputed. More recently, in 2012–2016, three novel human protoparvoviruses were discovered in stool samples of children with diarrhea and named bufavirus (BuV), tusavirus (TuV) and cutavirus (CuV). BuV has been associated with gastroenteritis and CuV with cutaneous T-cell lymphoma (CTCL), while more studies are needed to reveal if TuV really is a genuine human virus.

Classification

Parvoviruses are small non-enveloped icosahedral ($T = 1$) viruses with linear single-stranded (ss) DNA genomes forming double-stranded (ds) hairpin structures at both ends. The family *Parvoviridae* includes two subfamilies, *Parvovirinae* with 8 genera comprising viruses infecting vertebrates and *Densovirinae* with 5 genera comprising viruses infecting invertebrates, but with a third subfamily, *Hamaparvovirinae*, proposed with viruses of both vertebrates and invertebrates. Human parvoviruses are found in 5 different genera, *Erythroparvovirus*, *Dependoparvovirus*, *Tetraparvovirus*, *Bocaparvovirus* and *Protoparvovirus*, with human bocaviruses (HBoVs) and bufavirus (BuV), tusavirus (TuV), and cutavirus (CuV), belonging to the two latter genera, respectively. Virus species within the genera are monophyletic and their NS1 protein sequences (with some flexibility) are $> 30\%$ identical to each other but $< 30\%$ identical to those of other genera, which are general taxonomic criteria for parvoviruses. Characteristic for members of the *Bocaparvovirus* genus is a unique ~ 25 kDa nuclear protein, NP1, encoded in the middle of the genome. For both boca- and protoparvoviruses, the encapsidated linear ssDNA genomes are heterotetrameric and $\geq 90\%$ of genomes are of negative sense. The founder viruses of *Bocaparvovirus* are bovine parvovirus 1 (BPV1) and minute virus of canines (MVC), from which the genus name was created. *Protoparvovirus* is an older, but recently renamed, well characterized genus, including one of the first known parvoviruses, Kilham rat virus, discovered already in 1959. New viral members are being discovered at a rapid pace, but at the time of writing this review, there are 21 species in *Bocaparvovirus* and 11 in *Protoparvovirus*, with viruses from two species each infecting humans. HBoV1, HBoV3, a gorilla and a chimpanzee bocavirus belong, according to the NS1 amino-acid sequence identities, to the species *Primate bocaparvovirus 1*, and HBoV2 and HBoV4 belong to the species *Primate bocaparvovirus 2*. Similarly, all three BuV genotypes belong to *Primate protoparvovirus 1* and CuV to *Primate protoparvovirus 3*, while a rhesus monkey bufavirus founded the *Primate protoparvovirus 2* species. TuV has been proposed to found the species *Primate protoparvovirus 4*. The current status of parvovirus taxonomy and phylogenetic trees, can be seen at the “Relevant Websites section”.

Virion Structure

Parvoviruses are small (~ 25 nm) non-enveloped viruses with icosahedral $T = 1$ capsid symmetry. The capsid comprises thus 60 copies of the common C-terminal part of the capsid proteins (VPs), the vast majority of which is provided by the shortest VP (VP3 for HBoVs and VP2 for protoparvoviruses), and the minority (5%–10%) by the longer VP1 (and VP2 for HBoV) proteins. Typical to most parvoviruses, the short unique N-terminus of VP1, VP1u, carries phospholipase (PLA_2) activity, which is important in endosome escape. The capsid has multiple roles in parvovirus biology, including host cell recognition by binding to cellular receptors, intra-cellular trafficking by the activity of its PLA_2 motif, nuclear entry by its signaling sequences, genome packaging through its 5-fold cylinder, and host immune recognition of its neutralizing epitopes.

The HBoV major capsid protein is VP3 of ~ 60 kDa, and all three VPs seem to be translated from the same transcript, in a ratio of 1:1:10. However, for use as antigens or for structural studies, virus-like capsids (VLP) can be assembled based on VP3 alone. The major capsid protein in BuV, TuV and CuV is VP2 of the same size. The structures of HBoV1, HBoV3, HBoV4 and BuV1–3 VLPs, obtained by the baculovirus expression system, have been determined to high (~ 3 Å) resolution, by cryo-electron microscopy and 3D image reconstruction. The HBoV and BuV capsid cores are conserved and formed by an eight-stranded antiparallel β -barrel motif and an α -helix, similar to all other parvoviruses. The specific surface of the capsid is shaped by long amino acid loops between these secondary structures, containing ten variable regions (VR) of which VR-III and VR-IX have been identified as potential tropism determinants. Seemingly unique for the bocaparvoviruses, there is another α -helix within the surface loops. The HBoV and BuV capsids follow the typical parvoviral topology, including an open channel at the icosahedral 5-fold axes with a surrounding canyon, a depression at the 2-fold axes, and trimeric protrusions at the 3-fold axes. The HBoV 3-fold protrusions are less prominent than those of AAVs but more pronounced than those of parvovirus B19, and among the HBoVs, HBoV1 has the least prominent topology. Surprisingly, these trimeric 3-fold protrusions in BuV are separated, and therefore more similar to those of HBoV and B19V than those of animal protoparvoviruses, perhaps indicating a host-specific structural evolution. The conserved 5-fold channel is made by five β -strand ribbons forming a cylinder, through which DNA packaging is thought to occur. Unique for bocaparvoviruses is the presence of a density beneath the 5-fold axis that extends into the capsid interior. In both HBoV and BuV capsids, the location of the disordered VP1u and N-terminus of VP2 have not been structurally confirmed, but recent observations support the hypothesis that the N-termini would lie inside the capsid, from where a flexible VP1u could, when associated with a cell, be externalized through the 5-fold channel exposing its PLA_2 moiety. Four HBoV-specific antigenic epitopes have been mapped in the capsid, three being specific for HBoV1 at the 3-fold protrusions and the wall between the 2- and 5-fold axes, and a fourth HBoV1–4 cross-reacting epitope at the 5-fold axis. Structural analyses of TuV and CuV are ongoing.

Genome

All parvovirus virions have linear ssDNA genomes with dsDNA hairpin ends. Among viruses in the genus *Bocaparvovirus*, only the genomes of HBoV1, BPV1 and MVC have been sequenced in full length, including their terminal hairpins. The HBoV1 genome is 5543 nucleotides (nt) in length with nonidentical hairpin structures at the termini (Fig. 1(A)). In bocavirus virions, approximately over 90% of the viral genome are of negative sense. The HBoV1 left-end hairpin (LEH) is 140nt in length and is predicted to be ‘Y’ shaped with short axial “rabbit ears” and mismatches that cause an unpaired “bubble”. The LEHs of both MVC and BPV1 have

Fig. 1 Gene expression profile of HBoV1. The ssDNA genome of HBoV1 is depicted to scale in negative sense with transcriptional and RNA processing units: the P5 promoter, 5' splice-donor sites (D1, D1', D2, and D3) and 3' splice-acceptor sites (A1, A1', A2, and A3), the proximal and distal polyadenylation sites ((pA)p1/2 and (pA)d1/REH, respectively), and the 3' noncoding region (NCR). The left-end hairpin (LEH) and right-end hairpin (REH) structures of the genome are shown. Seven groups of HBoV1 mRNA transcripts are detected during infection, with either long-form mRNA (R_{XL}) that reads through the (pA)p site or short-form mRNA (R_{XS}) that is polyadenylated at the (pA)p site. R1 mRNA has a minor species (R1m) that is unspliced at the central small intron (D3–A3). Major open reading frames (ORFs) are depicted in colored boxes with the nucleotide number (nt) and amino acid (aa) of the start and stop codons indicated. Proteins expressed from each mRNA are indicated beside their respective mRNAs with molecular weight in kDa. *BocaSR* is diagramed, and is transcribed from the 3' NCR of nt 5199–5388 that bears an intergenic RNA polymerase III promoter (Pol III).

been isolated in two configurations, called flip and flop, suggesting that also the HBoV1 LEH should exist in both configurations. The right-end hairpin (REH) of MVC and BPV1, but not HBoV1, harbors sequences that have the potential to be folded into a cruciform structure near the end tip, although it is thermodynamically less favorable for BPV1. Notably, HBoV1 REH shares an identical 21-nt sequence with the MVC REH at the end, and the HBoV1 LEH shares two identical sequences of 6nt and 8nt, respectively, with the BPV LEH. Both the HBoV1 and MVC REHs are perfect duplex (palindromic) structures without any nucleotide mismatches and, therefore, only one configuration is present.

The intracellular duplex or replicative form of the HBoV1 genome is transcriptionally capable (Fig. 1(B)). The left half of the duplex genome encodes nonstructural, NS, proteins, and the right half encodes capsid, VP, proteins. The HBoV1 genome possesses two unique features among parvoviruses: (1) an additional NP1 protein is encoded from an open reading frame (ORF) lying in the middle of the genome, and (2) a viral noncoding RNA – bocavirus-transcribed small RNA (*BocaSR*), from the noncoding region (NCR) at the right-hand end of the duplex genome, after the VP ORF but before the REH. Parvoviruses utilize cellular DNA and RNA polymerases for replication and transcription, respectively. HBoV1 has only one (RNA polymerase II) promoter, P5, which transcribes a single precursor mRNA (pre-mRNA). The viral pre-mRNA is processed through alternative polyadenylation and

alternative splicing in the nucleus, which generates 7 groups of viral mRNA transcripts during infection (Fig. 1(B)). Notably, there is also an intergenic RNA polymerase III promoter at nt 5199–5338 that transcribes the 140-nt long *BocaSR* during infection.

While NS1 is essential to viral DNA replication, both NP1 and *BocaSR* enhance viral DNA replication. In *ex vivo* human airway epithelium cultured at an air-liquid interface (HAE-ALI), also NS2 is essential to virus replication, whereas NS3 and NS4 are dispensable. NP1 also plays an important role in VP expression by overcoming a blockage of the internal polyadenylation in the middle of the genome, and is essential to the splicing of viral pre-mRNA at the A3 acceptor site that lies in front of the (pA)p sites (Fig. 1(B)). *BocaSR* not only plays a role in viral DNA replication but also in the expression of NS1, NS2, NS3, and NP1 (but not NS4). The VP proteins constitute the capsid and allow packaging of the viral genome. Notably, VP1–3 are likely translated from a single mRNA, R6 or R7, and VP2 utilizes a noncanonical translation initiation site, GUG, at nt 3422 (Fig. 1(B)).

The human protoparvoviruses, BuV, TuV and CuV, have, similar to HBoVs, the same general genome organization as those of the other parvoviruses, with NS1 genes on the left half and VP genes on the right half of the negative-sense genome. In addition, BuV and CuV seem to have a small middle ORF, with unknown function. Contrary to HBoV and B19V, protoparvoviruses have two different promoters, one in the 3' end and the other in the middle of the genome, but only one termination site at the far-right end. The exact transcription maps for BuV, TuV and CuV have not been determined, however, they are most likely similar to those of the other better known animal protoparvoviruses.

Life Cycle

HBoV1 is detected in nasopharyngeal samples (NPS) of patients with acute respiratory tract infections (ARTI), suggesting that HBoV1 naturally infects human airways. Productive HBoV1 infection has been observed only in HAE-ALI. Although HBoV1 does not productively infect monolayer-cultured (proliferating) human cells, including human embryonic kidney 293 (HEK293) cells, HEK293 cells fully support replication of the HBoV1 duplex genome – delivered by transfection of a full-length plasmid clone of HBoV1 (pHBoV1) – and produces progeny virions that are fully infectious in HAE-ALI, but not in monolayer-cultured airway epithelial cell lines, such as A549 and BEAS-2B cells. HAE-ALI cultures generated from primary or repopulating primary human bronchial/tracheal epithelial cells, as well as immortalized human airway epithelial cells (CuFi-7), support productive infection of HBoV1. Recently, it has been reported that Caco-2 cells, derived from human colon cancer, can be infected with HBoV1, but only after polarization/differentiation.

HBoV1 can infect HAE-ALI cultures through both the apical and the basolateral sides, suggesting that the (unknown) virus receptor is expressed on both sides of the airway epithelia (Fig. 2, steps 1–2). As with other parvoviruses (e.g., B19V, CPV, AAV2, and MVM), HBoV1 likely enters the cells through receptor-mediated endocytosis, and intracellularly traffics from early endosome to late endosome (Fig. 2, steps 3). Virions may directly disrupt the nuclear envelope or be transported through the nuclear pore to translocate into the nucleus (Fig. 2, step 4). Within the nucleus, the viral genome is released and likely recognized by the cellular repair machinery (Fig. 2, step 6). Then, the ssDNA viral genome is converted into a duplex form (Fig. 2, steps 7a and 7b). In polarized HAE cells that are mitotically terminated (differentiated), cellular DNA repair DNA polymerases η/κ are involved in HBoV1 DNA replication. This has not been shown for other parvoviruses. It is thus believed that the Y-family polymerases η/κ synthesize the complementary strand, utilizing the 3'-OH hairpin end as primer. After expression from the duplex genome, NS and NP1 proteins are associated with the viral genome for viral DNA replication (Fig. 2, steps 12–16). NS or NP1 proteins are likely required for genome packaging as well (Fig. 2, steps 16–18); however, they are not packaged into the mature virions themselves. The viral DNA replication process involves complex hairpin structure transfers and protein-genome interactions, which produces viral DNA intermediates in various lengths and structures (Fig. 2, steps 12–16). Viral pre-mRNA is transcribed from the duplex form genome and further processed to generate NS-, NP-, and VP-coding mRNAs (Fig. 2, step 8). Capsid proteins VP1, VP2, and VP3, produced in the cytoplasm, are assembled into oligomers before translocating into the nucleus (Fig. 2, steps 10 and 11). Empty capsids are assembled in the nucleus after which viral ssDNA is encapsidated (Fig. 2, steps 17–18). Eventually, the mature virions are released from the nucleus into the cytoplasm and transported out of the infected cells (Fig. 2, steps 19–20), which undergo pyroptotic cell death. BuV, TuV and CuV have not yet been propagated in cell culture.

Epidemiology

Human Bocaviruses

HBoV1, being a respiratory virus, is most likely transmitted by the respiratory route, whereas HBoV2 and 3 are considered enteric and are most likely transmitted by the fecal-oral route. Findings supporting this are mainly that HBoV1 DNA is detected by quantitative (q)PCR in high amounts in airway samples during the acute phase of ARTI, whereas HBoV2–4 seldom are found in such samples but are detected in stool. HBoV1 is most common in children between 0.5 and 5 years of age, with a mean age of infection of 2 years. HBoV1 DNA is detected in 2%–20% of NPS of children with upper or lower ARTI, but due to its persistence in the airways for up to a year, it may be detected in lower DNA loads also in healthy children. The most common HBoV in stool samples is HBoV2 that has been found in 1%–20% of stools of both symptomatic and non-symptomatic subjects, followed by HBoV1, HBoV3 and HBoV4. None of these have, however, indisputably been shown to cause gastroenteritis. Further, HBoV4 is too

Fig. 2 The infection life cycle of HBoV1. HBoV1 infection of human airway epithelium cultured at an air–liquid interface (HAE-ALI) is illustrated with a polarized airway epithelial cell featured with the apical side towards the airway lumen, basolateral layers, columnar cilia, and adherent junction molecules. Each step of the virus life cycle is explained in the text. Ligase, an unknown cellular DNA ligase; -ssDNA, negative single-stranded DNA; pol η/κ , DNA repair DNA polymerase η and κ .

rare to state anything of its transmission, pathogenicity or tissue tropism. Contrary to B19V, none of the HBoVs seem to be transmitted by blood or blood products, even though a short viremic phase does occur during acute infection and HBoV1 DNA is infrequently detected in donated blood. Besides serum, respiratory and enteric samples, HBoV DNAs have been detected also in saliva, urine, cerebrospinal fluid (CSF), tonsils, and intestinal biopsies, as well as in environmental river water and in sewage. HBoV1 DNA is globally detected throughout the year with no obvious seasonality observed, however, the long persistence of HBoV1 DNA in the airways makes such studies problematic.

HBoVs cause systemic infections, likely leading to immunity. Most HBoV1-specific antibody responses are strong and life-long, but ~30% are weaker and some may be totally nonexistent. Further, the IgG responses against the enteric HBoVs are generally

weaker and even more prone to waning than those against HBoV1. This variation is due to both cross reactivity between the HBoVs and to an immunological phenomenon called “original antigenic sin” (OAS). If a person has been infected by HBoV2 earlier in life, his/her current HBoV1 infection might not induce HBoV1-specific IgG responses, leading to a false negative IgG result and a lower seroprevalence. Despite these challenges, the seroprevalence of HBoV1–4 in Finland already at the age of 6 have been determined to be 80%, 50%, 10% and ~0%, and in China among adults to 67%, 50%, 40% and 1.4%, respectively, indicating that HBoV1 is the most common human bocavirus circulating worldwide. The median age of infection is 2 years for HBoV1 and slightly lower for the enteric HBoVs, while in adults and the elderly, HBoV infections are much less frequent.

Human Protoparvoviruses

BuV, TuV, and CuV were all discovered by metagenomics in stools from children with diarrhea. The BuV DNA prevalence is between 0% and 4% in stools of diarrheic patients from Africa, Europe, Asia, and South America, and viral DNA can be found also in river water. In a study from Finland, also close to 1000 nasal swabs were studied for BuV DNA, only one being positive, indicating that BuV is not a respiratory virus. All BuV sequences typed to-date have been of genotype 1 or 3, while genotype 2 DNA has been identified only in the stool of a single child from Burkina Faso, described in the original discovery report. Likewise, TuV DNA has also been detected in a single pediatric stool sample, obtained from Tunisia, whereas the CuV genoprevalence was 1%–2% among stools from Brazil and Botswana.

The three BuV genotypes, sharing only 65%–73% VP2 amino-acid identity, can be separately identified in EIAs and are thus also considered different serotypes. The global BuV seroprevalence pattern is strikingly different, varying among adults from 2% to 4% in Finland and the USA to 56%–85% in Kenya and the Middle East. The predominant genotype in Kenya was BuV-3 and that in the Middle East BuV-1, whereas BuV-2 was the second-most prevalent genotype on both continents. This finding contrasts the PCR findings, where BuV-2 DNA has been found in only one sample. TuV IgG was not found in the sera from any of the four continents, while CuV IgG was evenly distributed with a seroprevalence of 0%–6%. BuV-2 and CuV VP2s are more similar to each other than those of BuV-1 and -3, and they therefore need blocking by a competition EIA not to show considerable cross reactivity of IgG.

Clinical Features

Human Bocaviruses

HBoV1 is one of the most common respiratory viruses detected in NPS of children with ARTI. However, HBoV1 DNA is frequently (20%–80%) detected together with other respiratory pathogens and it is also detected in NPS of healthy children. In the early studies, researchers were therefore questioning the clinical significance of HBoV1 in ARTI and many considered it a bystander virus. Later, this high prevalence of HBoV1 DNA was shown to be due to virus persistence in the nasopharynx for several weeks to up to a year after acute infection, during which time the child may have several other respiratory tract infections. Consequently, the mere presence of this virus in the airways, determined by sensitive qualitative PCRs, cannot be a reliable marker for a HBoV1 etiology in the current ARTI. Comprehensive clinical studies, applying monodetection and/or more accurate diagnostic markers, including serology, qPCR, reverse transcription (RT)-PCR and antigen detection, have since provided convincing evidence of HBoV1 being a true respiratory pathogen in children.

HBoV1 may cause both upper or lower ARTI, most often in children of 0.5–5 years of age, while smaller infants are mostly protected by passive maternal antibodies. The most frequent clinical features are those associated with the common cold, bronchiolitis, pneumonia, and exacerbations of asthma. The symptoms do not differ from those of other viral ARTIs; cough, fever, rhinitis, and wheezing. In addition, acute otitis media and diarrhea are often reported during HBoV1 infection and viral DNA has been detected in middle-ear fluids and stool. Typical signs of pneumonia, with patchy or interstitial infiltrates in chest radiographs, hyperinflation and atelectasis, as well as hypoxia and tachypnea are frequently seen in HBoV1-caused lower ARTI. HBoV1 has further been the sole finding also in several life-threatening infections with respiratory failure demanding intensive care with mechanical ventilation.

In adults, HBoV1 DNA detections in airway samples are infrequent, possibly due to the high seroprevalence, but usually associated with respiratory symptoms. Summarizing 5 major studies in China with > 12,000 adult ARTI patients, the prevalence of HBoV1 DNA in airway samples was 0.3%. In one study on Finnish elderly adults (> 65 years of age, with a mean age of 83 years), no acute HBoV1–4 infections were recorded among 438 episodes of ARTI, as diagnosed by serology and only 2 (0.5%) had HBoV1 DNA in their respiratory samples. Among these patients, 88% were HBoV1 IgG seropositive. A striking difference between these elderly adults and children was the low prevalence of HBoV1 (0%) and high prevalence of RSV (7%) genome detections in the samples of 283 asymptomatic elderly controls.

The four HBoVs have also been found in up to 25% of diarrheic stool samples, but neither their DNA loads nor prevalence suggests a causal association with AGE. In most studies equally often HBoV DNA is detected in stools of symptomatic as of asymptomatic children. A prolonged excretion of HBoV1 and 2 in stool has furthermore been reported, making disease associations difficult. Nevertheless, one case is reported of a life-threatening hypovolemic shock due to diarrhea associated with a disseminated HBoV1 infection in an immunocompromised 9-year-old boy, with no other pathogens detected.

HBoV1, HBoV2, and HBoV3 have infrequently been detected, as sole microbes, in CSF of patients with severe encephalitis, indicating a possible role in infections of the central nervous system. In a HBoV2 DNA-positive CSF sample also typical parvoviral virions were detected by electron microscopy; the child was further seronegative but viremic. The severity of symptoms in the HBoV-positive patients did not differ from those of patients with other virus findings in CSF (dengue-, echo- or adenovirus). In addition, there are case reports of HBoV-associated myocarditis and hepatitis. A 13-month-old girl had a fatal subacute myocarditis with HBoV2 DNA detected in NPS, plasma, urine, ascites, mesenteric node, skeletal muscle, and lung, and she died of heart failure. A previously healthy 2.5-year-old girl had bronchiolitis and hepatitis with high-load HBoV1 viremia as sole finding, and another 7-month-old boy with an underlying T-cell deficiency, had hepatitis with HBoV1 DNA in consecutive NPA, feces, urine, and serum samples and with diagnostic increases in both HBoV1 IgM and IgG. These cases suggest that the full picture of the clinical impact of HBoVs is still to be revealed.

Human Protoparvoviruses

Very little is known about the clinical pictures of BuV, TuV, and CuV infections. BuV has been shown to associate with diarrhea, since its DNA has been detected by PCR only in diarrheic stools, while non-diarrheic stools all have so far been PCR negative. However, the frequencies as well as viral loads have been low, suggesting a nonsignificant role of BuV in gastroenteritis. No further TuV and CuV PCR studies of stool samples have been reported, leaving their relationship with gastroenteritis open. CuV DNA has, however, in three separate studies been detected in skin lesions of cutaneous T-cell lymphoma patients, but not in skin biopsies of healthy subjects, reaching statistical significance. It cannot be proven at this time, whether or not this association is causal or consequential. Parvoviruses are usually not directly oncogenic, but they may cause chronic inflammation possibly leading to cell transformation. CuV DNA has infrequently been detected also in melanoma lesions and in both healthy and malignant skin biopsies of immunocompromised transplant patients.

Pathogenesis

As animal models of HBoV1 infection are currently not available, the respiratory pathogenesis of HBoV1 is not well understood and thus is limited to HBoV1 infection in the ex vivo HAE-ALI culture model. HBoV1 infection of polarized HAE-ALI cultures is persistent, and can last 45 days with release of progeny virions, or as long as the ALI cultures can be maintained. The infection induces progressive airway epithelial damage with disruption of the tight junction barrier, thinning of the epithelium, loss of cilia, and epithelial cell hypertrophy indicated by enlarged nuclei. HBoV1 infection induces pyroptotic cell death of airway epithelial cells, represented by activation of caspase 1 but not of caspase 3, as well as an increase in the expression of cytokines IL-1 and IL-18. The pyroptosis induced by HBoV1 infection is mediated by the NLRP3 (NLR family pyrin domain containing 3 protein)-ASC (apoptosis-associated speck-like protein containing a CARD)-caspase-1 inflammasome-induced pathway.

Mechanistically, HBoV1 infection upregulates the expression of the anti-apoptotic genes *BIRC5* (Survivin, also called baculoviral inhibitor of apoptosis repeat-containing 5) and *IFI6* (interferon alpha inducible protein 6), which inhibit HAE cell apoptosis, and therefore the infected cells die via pyroptosis. Notably, pyroptosis does not inhibit HBoV1 replication. HBoV1 infection-induced chronic inflammation may serve to promote its persistent infection. HBoV1-infected patients are mostly young children, still with maturing immune systems. If HBoV1-infected cells are not quickly eliminated by effective immune responses, the intensifying inflammation cycle could possibly even lead to lung tissue injury in HBoV1-infected young children.

Pyroptosis is an inflammasome-mediated cell death with release of active IL-1, IL-18, and gasdermin D (GSDMD), which cause the cell to swell and eventually lyse. Therefore, HBoV1 infection-caused cell death is not limited to the infected cells but also spreads to the entire epithelia cultured on the insert, including uninfected cells of the inserts. It is currently unknown which viral components are sensed as pathogen-associated molecular patterns (PAMPs) by any pattern recognition receptors (PRRs) or which damage-associated molecular patterns (DAMPs) are generated into the cytosol during infection. Further studies are warranted to examine the nature of cell death in clinical specimens such as cells in airway washes from patients with monoinfection of HBoV1.

Diagnosis

Diagnosis of HBoV1 ARTI is challenging because of viral persistence in the airways long after infection (Fig. 3). Qualitative PCR of NPS, the predominantly used diagnostics for ARTI, is therefore insufficient. For an accurate diagnosis of acute HBoV1 infection, a combination of many different approaches is needed. One such approach is quantitative PCR, which gives a better estimate of how recently the infection began; a high viral load (typically over 10^4 or 10^6 copies/ml) would therefore suggest an acute HBoV1 infection. However, as verified by serology, about a third of patients with low viral load and even a few symptomatic patients with HBoV1 PCR-negative NPS, still had an acute HBoV1 infection and conversely, some patients with high loads of HBoV1 DNA in NPA, yet do not have acute infection. Obviously, if no other pathogens are detected, it strengthens the probability of an HBoV1 etiology, but again, ~60% of patients with other pathogens co-detected, experience also true acute HBoV1 infections. Another useful diagnostic method for respiratory samples is reverse transcription (RT)-PCR for detection of viral mRNA. Viral transcripts are

Fig. 3 Clinical course of HBoV1 infection. Appearance of respiratory symptoms, of HBoV1 DNA, mRNA and antigen in the nasopharynx, of HBoV1-specific DNA, IgM and IgG in blood, as well as increase of IgG avidity, after acute primary HBoV1 infection. The exact time of onset of symptoms related to time of infection (i.e., incubation time) is unknown, but has here been estimated based on the antibody kinetics and proportion of the other diagnostic markers in wheezing children with and without seroconversion. NPS, nasopharyngeal samples; IgM, immunoglobulin M; IgG, immunoglobulin G.

expressed mostly in the acute phase of HBoV1 infection and can thus be considered an indirect marker of virus replication and ongoing infection. By a novel commercial antigen assay, also viral capsid protein can be detected in NPS, which would indicate an acute phase of infection. The specificity is good but the sensitivity is lower than for the PCR-based assays.

When an accurate diagnosis of HBoV1 respiratory tract infection is required, also serum (or plasma) is an important sample type. HBoV1 causes a systemic infection resulting in a short-phase viremia, and can therefore, during the very acute phase, be found by PCR in blood or serum. HBoV1 DNA has, however, been shown to persist longer in some individuals, slightly decreasing the clinical specificity. The most compelling evidence perhaps for an acute HBoV1 infection is, however, the detection of HBoV1-specific IgM together with a seroconversion or a $\geq$ four-fold increase of IgG in paired serum samples, taken at the acute phase and at the convalescent phase two weeks later (Fig. 3). A low IgG avidity (even in a single IgG-positive sample) further verifies the acute HBoV1 infection, whereas a high IgG avidity indicates past immunity from a prior infection a few months to several years ago. The IgG-avidity EIA thus further increases the diagnostic value of serology. Nevertheless, two issues hamper the reliability of serology. First, the four HBoVs induce cross-reacting antibodies to common epitopes, showing reactivity in all four HBoV EIAs, despite only one of them is specific reactivity. Such cross-reactivity can, however, be avoided by blocking the HBoV1–4 common antibodies from binding by adding the heterotypic VLP antigens to the serum prior to the EIA, leaving only the antibodies to specific HBoV1 epitopes for measurement. Secondly, the four related HBoVs may occasionally interact immunologically resulting in OAS, a phenomenon described above (Epidemiology), perhaps leading to a slightly decreased negative predictive value. However, this OAS effect seems to occur more often in past immunity than in recent infection.

Taken together, due to virus persistence in the airways, the detection of HBoV1 DNA by a qualitative PCR in NPS is insufficient. The most accurate diagnosis of acute HBoV1 respiratory tract infection is obtained by combining different diagnostic approaches; HBoV1-DNA monodetection, high viral-DNA load, and detection of viral mRNA or antigen in respiratory specimens, viral DNA detection in serum, and detection of HBoV1-specific IgM coupled with seroconversion or ≥ 4 -fold increase in paired sera of HBoV1-specific IgG antibodies with low avidity.

For the human protoparvoviruses, only qPCR and IgG EIA methodology so far exist, but development of IgM EIAs is ongoing for future clinical studies.

Prevention

Since HBoV1 is transmitted by close contact, droplets or aerosols, and HBoV2–4, BuV and CuV possibly by the fecal-oral route, standard hygienic practices like hand washing with soap may reduce spreading the virus. However, alcohol-derived gels are less effective against non-enveloped parvoviruses. Avoiding large crowds in closed areas during the cold seasons, may also diminish the risk of getting respiratory tract infections. Currently there are no vaccines or specific medication available for human parvovirus infections.

Glossary

Apoptosis A form of programmed cell death that occurs in multicellular organisms. Biochemical events lead to characteristic cell changes (morphology) and death.
Autophagy The natural, regulated mechanism of the cell that removes unnecessary or dysfunctional components. It allows the orderly degradation and recycling of cellular components.
ER stress A cellular process that is triggered by a variety of conditions that disturb the folding of proteins in the endoplasmic reticulum.
Innate immunity Refers to nonspecific defense mechanisms that come into play immediately or within hours upon pathogen recognition in the body. These mechanisms include physical barriers such as skin, chemicals in the blood, cytokine production and immune cells that attack foreign cells in the body.

Mitogen-activated protein kinase Serine-threonine protein kinases, important molecules in mediating the signal transduction from cell surface to nucleus, regulating cellular activities such as gene expression, mitosis, differentiation, and cell survival/apoptosis.
Type I interferon A large subgroup of interferon proteins that help regulate the activity of the immune system, and a pleiotropic cytokine with antiviral, antitumor and immunoregulatory functions.
Unfolded protein response A cellular stress response related to the endoplasmic reticulum stress. It has been found to be conserved between all mammalian species, as well as yeast and worm organisms.
Viroporin A group of small hydrophobic viral proteins that tend to oligomerize to form hydrophilic pores or ion channels in cellular membrane.

Background

The first human coronavirus (HCoV), strain B814, was isolated in 1965 from the nasal discharge of a patient with a common cold. Since then, more than 30 additional strains were identified. Among them, the prototypic strain HCoV-229E (named after a student specimen coded 229E) was isolated using standard tissue culture. HCoV-OC43 (Organ Culture 43) was later recovered using tracheal organ culture and found to be serologically distinct from HCoV-229E. These two viruses were the focus of HCoV research

Fig. 1 The updated classification scheme of HCoVs according to the ICTV.

in the following years, until the emergence of the highly pathogenic severe acute respiratory syndrome coronavirus (SARS-CoV) in 2002–2003. In the post SARS era, two more HCoVs were identified. HCoV-NL63 (NetherLand 63) was isolated from the aspirate of a 7-month-old infant with bronchiolitis in 2004, whereas HCoV-HKU1 (Hong Kong University 1) was isolated from a Hong Kong patient with pneumonia in 2005. Since then, two more zoonotic HCoVs have emerged, namely as the Middle East respiratory syndrome coronavirus (MERS-CoV) and the 2019 novel coronavirus (2019-nCoV, a.k.a. SARS-CoV-2). Unlike SARS-CoV, MERS-CoV and SARS-CoV-2 that are associated with severe respiratory disease, the four common HCoVs (229E, OC43, NL63, and HKU1) generally cause mild to moderate upper-respiratory tract illness, presumably contributing to 15%–30% of cases of common colds in human.

Classification

On the basis of the 10th International Committee on Taxonomy of Viruses (ICTV) report, coronaviruses are classified under the order *Nidovirales*, suborder *Cornidovirineae*, family *Coronaviridae*, subfamily *Orthocoronavirinae* (Fig. 1). According to serology studies and genomic analysis, *Orthocoronavirinae* is further divided into four genera: *Alphacoronavirus*, *Betacoronavirus*, *Gammacoronavirus*, and *Deltacoronavirus*. Under the genus *Alphacoronavirus*, HCoV-229E and HCoV-NL63 belong to the subgenus *Duvinacovirus* and *Setracovirus*, respectively; under the genus *Betacoronavirus*, both HCoV-OC43 and HCoV-HKU1 belong to the subgenus *Embecovirus*.

Virion Structure

Under the electron microscope, coronavirus virions are spherical or pleomorphic. Coronavirus particles are enveloped, about 80–120 nm in diameter, with club-like projections of the spike (S) protein decorating the surface. In some *betacoronaviruses*, including HCoV-OC43 and HCoV-HKU1, shorter projections of the hemagglutinin-esterase (HE) protein are also observed. The viral envelope is supported by the membrane (M) protein and contains a small amount of the envelope (E) protein. Inside the viral envelope, the genome is bound by the nucleocapsid (N) protein to form a helical symmetric nucleocapsid. The common structural and functional features of HCoV structural proteins are briefly summarized as follows.

The S protein is a type I transmembrane protein, with a molecular weight of 128–160 kDa before glycosylation and 150–200 kDa after N-linked glycosylation. As a class I viral fusion protein, the S protein forms homotrimer and is cleaved by host proteases into a S1 subunit for receptor binding and a S2 subunit for membrane fusion. The ectodomain of the S protein is also modified by disulfide bonds, whereas the very short cytosolic tail is modified by palmitoylation. The S protein is the major determinant of host and tissue tropism, and may also contribute to viral pathogenesis by activating the endoplasmic reticulum (ER) stress response.

The HE protein is also a type I transmembrane protein, about 48 kDa before glycosylation and 67 kDa after N-linked glycosylation. It forms homodimer via disulfide bonds. With its sialic acid-binding hemagglutinin activity, the HE protein may serve as a cofactor of S protein and facilitate virion attachment. Additionally, as it possesses esterase activity that removes acetyl groups from O-acetylated sialic acids, it has been postulated to have a role as a receptor-destroying enzyme that facilitates the

release of progeny virions from nonpermissive host cells, thereby enhancing virion spreading in the extracellular milieu. In fact, the HE protein of HCoV-HKU1 mediated receptor-destroying enzyme activity specific to the *O*-acetylated sialic acids recognized by its own S protein.

The M protein (25–30 kDa) is the most abundant structural protein and possesses three transmembrane domains. The short N-terminal ectodomain of the M protein is modified by *O*-linked glycosylation in HCoV-OC43 and some animal coronaviruses including mouse hepatitis virus (MHV) and bovine coronavirus (BCoV). However, in HCoV-229E, HCoV-NL63, and most other coronaviruses, the ectodomain of M protein is modified by N-linked glycosylation. The M protein forms homodimer and interacts with other viral structural proteins to orchestrate the assembly of the coronavirus particle. This protein may also contribute to viral pathogenesis. For example, retinoic acid-inducible gene 1 (RIG-I)-dependent induction of type I interferon (IFN) is observed in cells overexpressing the M protein of SARS-CoV but not HCoV-HKU1.

The E protein is a small (8–12 kDa) integral membrane protein found in low amounts in the virion. Current evidence strongly suggests that the E protein adopts an N-ecto/C-endo topology with one transmembrane domain. The SARS-CoV E protein is modified by N-linked glycosylation and three cysteine residues in its endodomain are modified by palmitoylation. Additionally, the E protein of SARS-CoV and avian infectious bronchitis coronavirus (IBV) has been shown to form homopentamers with ion channel (IC) activity. The IC activity may modulate the process of virion release and contribute to viral pathogenesis. Although the deletion of the E gene is not lethal for SARS-CoV, the mutant virus is severely defective in virion morphogenesis and attenuated *in vivo* compared with the wild type control.

Underneath the viral envelope, the N protein (43–50 kDa) forms dimer and binds to the genomic RNA in a beads-on-a-string fashion, forming a helically symmetric nucleocapsid. In SARS-CoV and other coronaviruses, the N protein is phosphorylated by cellular kinases such as glycogen synthase kinase 3 (GSK3) and ataxia-telangiectasia mutated and Rad3-related. Other modifications such as SUMOylation, ADP-ribosylation, and proteolytic cleavage by caspases has also been demonstrated in the N protein of some coronaviruses. The N protein facilitates RNA packing and is involved in many other processes, including viral genome replication and evasion of the immune response.

Genome

With a single-stranded, positive-sense RNA genome containing approximately 27 to 32 kilobases (kb), coronavirus has the largest viral RNA genome described so far. The genome sizes are approximately 27.5 kb for HCoV-229E and HCoV-NL63, and more than 30 kb for HCoV-OC43 and HCoV-HKU1 (Fig. 2). Because the genomic RNA harbors a 5'-cap structure and a 3'-polyadenylate tail, it can act directly as a messenger RNA (mRNA) encoding the viral replicase. Additionally, the genome also serves as a template for RNA replication and the genome is packed into progeny virions. There are two untranslated regions (UTRs) flanking the coding region. The 5'-UTR is 292, 210, 286, and 205 nucleotides long in HCoV-229E, -OC43, -NL63, and -HKU1, respectively, and contains a leader sequence (~70 nucleotides long) at its 5'-terminus. At the other end of the genome, the 3'-UTR is 462, 288, 287, and 281 nucleotides long in HCoV-229E, -OC43, -NL63, and -HKU1 respectively, and it contains a highly conserved octameric sequence ~70 nucleotides upstream from the poly(A) tail.

The HCoVs replicase gene comprises the 5'-two thirds of the genome and is made up of two overlapping open reading frames (ORFs)—ORF1a and ORF1b. ORF1a is directly translated from the RNA genome, producing the polyprotein pp1a; whereas the translation of ORF1b requires a programmed ribosomal frameshift near the 3' end of ORF1a, leading to the production of polyprotein pp1ab. The autoproteolytic cleavage of pp1a and pp1ab then gives rise to 16 non-structural proteins (nsp1–16).

Fig. 2 Genome structure of human coronaviruses (HCoVs) – HCoV-229E, HCoV-OC43, HCoV-NL63 and HCoV-HKU1. The open reading frame 1a (ORF1a) and ORF1b are represented as shortened navy blue-boxes. The genes encoding structural proteins spike (S), envelope (E), membrane (M), nucleocapsid (N), and hemagglutinin-esterase (HE) are shown as orange boxes. The genes encoding accessory proteins are shown as dark gray boxes.

The remaining one third of the HCoV genome contains ORFs for viral structural proteins in the order of 5'-(HE)-S-E-M-N-3', as well as several accessory proteins that are distinct among HCoVs of different species and genus. Specifically, HCoV-229E encodes two accessory proteins 4a and 4b; HCoV-OC43 encodes three accessory proteins ns2a, ns12.9 (a.k.a. ns5a), and protein I (a.k.a. N2 or N internal ORF protein); HCoV-NL63 encodes a single accessory protein 3; and HCoV-HKU1 encodes two accessory proteins: protein 4 and protein I. Although these accessory proteins are dispensable for viral replication in cell culture, they may be involved in viral pathogenesis and contribute to virulence in vivo. Unlike the viral replicase, structural proteins and accessory proteins are translated from a 3'-nested set of subgenomic RNA (sgRNA) species. The coding sequences of some accessory proteins overlap with those of the structural proteins, but are translated in distinct reading frames. In fact, the accessory gene encoding protein I of HCoV-OC43 and HCoV-HKU1 are encoded internally of the N genes.

Non-Structural Proteins

The HCoV polyproteins pp1a and pp1ab are autocatalytically processed by viral proteases into 16 non-structural proteins. Nsp1, the most N-terminal cleavage product of the polyproteins, has been shown to suppress host protein synthesis and IFN response.

Nsp3 encodes one or two papain-like proteases (PLpro). Nsp3 of the four common HCoVs contains two PLpro domains (PLP1 and PLP2), whereas the nsp3 of SARS-CoV and MERS-CoV contains only one PLpro domain. In general, PLP1 processes at cleavage site 1 to release nsp1, whereas PLP2 is responsible for the processing at both cleavage sites 2 and 3 to release nsp2 and nsp3. The deletion of PLP2 is lethal, whereas the proteolytic activity of PLP1 is dispensable for HCoV-229E replication. Notably, a recent study reported that ectopic expression of HCoV-NL63 PLP2 induces proteasomal degradation of p53, thereby inhibiting p53-dependent production of type I IFN and the innate immune response.

Following the translation of ORF1a and ORF1ab, nsp5 is properly folded within the context of the replicase polyprotein and orchestrates its own autoproteolytic processing. Nsp5 cleaves pp1a/pp1ab at as many as 11 sites to produce a total of 13 mature proteins, and is therefore indispensable for virus replication. Nsp5 is also referred to as the coronavirus main protease (Mpro).

Nsp6 of some coronaviruses, such as IBV, MHV, or SARS-CoV, activates the formation of autophagosomes from the ER via an omegasome intermediate. Nsp3, nsp4, and nsp6 are also responsible for remodeling cellular membranes to form double-membrane vesicles (DMVs) or ER spherules, onto which the coronavirus replication-transcription complex (RTC) is assembled and anchored.

The complex of HCoV-229E nsp7 and nsp8 is capable of synthesizing short RNA strands of ~6 nucleotides. Coronavirus nsp8 protein also has template-dependent RNA polymerase activities resembling those of RNA primases or even canonical RNA-dependent RNA polymerases (RdRP). Current evidence suggests an essential cofactor function of nsp7 and nsp8 for the RNA-dependent RNA polymerase activity of nsp12. In a recent study, it is found that nsp8 of HCoV-229E has a metal ion-dependent RNA 3'-terminal adenylyl transferase (TATase) activity, when a partially double-stranded RNA with a short 5' oligo-U sequence is provided as the template strand. This supports the notion that nsp8 may catalyze the 3'-polyadenylation of HCoV genomes.

Nsp9, a single-stranded DNA/RNA-binding protein which exists as a dimer in physiological situations, has been found to be indispensable for virus replication based on reverse-genetics experiments. Nsp10 is a double-stranded RNA-binding zinc-finger protein. Nsp7, nsp8, nsp9, and nsp10 are all closely associated with the replication complex built around the RNA-dependent RNA polymerase (nsp12).

Nsp13 separates the double-stranded replicative intermediates to provide single-stranded templates for RNA synthesis. HCoV-229E nsp13 contains an N-terminal zinc-binding domain and a C-terminal superfamily 1 helicase domain. It exhibits a variety of enzymatic activities including NTPase, dNTPase, and RNA/DNA helicase activity. Using the NTPase active site, this protein also has an RNA 5'-triphosphatase activity, which may be involved in the capping of viral RNAs.

Nsp14 demonstrates exoribonuclease (ExoN) activities. RNA viruses generally have high mutation rates that allow for rapid viral adaptation in response to selective pressure. Nsp14-ExoN is the first proofreading enzyme identified for an RNA virus, and it functions together with other CoV replicase proteins to perform the crucial role of maintaining CoV replication fidelity.

Nsp15 is an endoribonuclease (NendoU) and a type I interferon antagonist. HCoV nsp15-NendoU can excise both single- and double-stranded RNA and specifically recognize uridylylates to produce 2-3'-cyclic phosphodiester products, thereby preventing the activation of the host innate immune response.

Nsp16 has a 2'-O-methyltransferase activity. The 2'-O-methylation capping protects viral RNA from recognition by melanoma differentiation-associated protein 5 (MDA5) and thus prevents MDA5-dependent production of type I interferon in virus-infected cells.

Accessory Proteins

Although not essential for viral replication in cell culture, coronavirus accessory proteins may play in vivo functions that have not yet been fully elucidated. Most HCoV accessory proteins are genus-specific and show low homology to known proteins. But an accessory gene between the S and E gene is encoded by three HCoVs (3a of SARS-CoV, 4a of HCoV-229E, and ns12.9 of HCoV-OC43), suggesting a conserved role during HCoV infection. Indeed, all three proteins have been shown to serve as viroporins that regulate viral replication. Viroporins are oligomeric hydrophobic viral proteins that form and insert ion channels into the host cell membrane. The HCoV-OC43 ns12.9 protein is a recently identified viroporin that facilitates virion

Fig. 3 HCoV replication cycle. HCoV infection is initiated by binding of virions to cellular receptors, which drives the conformational change in the S2 subunit in S, promoting the fusion of the viral and cell plasma membrane. The gRNA serves as the template for translation of polyproteins pp1a and pp1ab, which are cleaved to form nsps. Nsps induce the rearrangement of cellular membrane to form DMVs, where the viral RTCs are anchored. Full-length gRNA is replicated via a negative-sense intermediate, and a nested set of sgRNA species are synthesized by discontinuous transcription. These sgRNAs encode viral structural and accessory proteins. The viral products produced will be assembled in the ERGIC, and bud out as a smooth-wall vesicle to the plasma membrane to egress via exocytosis. Host factors that promote infection and inhibit infection are highlighted in green and black, respectively.

morphogenesis and pathogenesis. The expression of important mediators of innate immune response was downregulated in cells expressing of HCoV-OC43 ns12.9, presumably due to inhibited promoter activity of ISRE, IFN- β , and NF- κ B.

Interestingly, because of a scenario in which HCoV-229E acquired an out-of-frame insertion or deletion, instead of an ORF4a and ORF4b, an intact ORF4 was present in some HCoV-229E clinical isolates. ORF4a of HCoV-229E was expressed in infected cells and localized at the ER/Golgi intermediate compartment (ERGIC). The ORF4a protein formed homo-oligomers through disulfide bridges and possessed ion channel activity in both *Xenopus* oocytes and yeast.

The NS2 protein of HCoV-OC43 has cyclic phosphodiesterase activity, which may modulate cAMP-mediated signaling and important physiological processes such as lipid metabolism and apoptosis. Finally, although the accessory protein encoded by HCoV-NL63 ORF3 appears to be nonessential in cell culture, there were differences in RNA synthesis, protein expression, plaque morphology, and virus growth in cells infected with the ORF3-deleted mutant compared with the control.

Life Cycle

The replication cycle of HCoV can be arbitrarily divided into five steps: attachment to host cells, viral entry and uncoating, expression of the viral replicase and formation of the replication-transcription complex, viral RNA synthesis, and virion assembly and release. Each step will be briefly introduced as follows (Fig. 3).

Attachment

Coronavirus infection is initiated by binding of virions to cellular receptors. The S protein includes two functional domains: S1 (bulb) is the part binding to the receptor(s) and S2 (stalk) is responsible for fusion between virion and cell membranes. The receptor-binding domain (RBD) of S1 varies among different coronaviruses. RBDs of HCoV-229E, HCoV-NL63 and HCoV-HKU1 are located in the C-terminal region but not the N-terminal domains of the respective S1 subunits.

Receptor binding is critical to initiate viral infection. HCoV has been shown to use either cellular proteins or carbohydrates displayed on the plasma membrane as receptors. Interestingly, all known protein receptors for HCoVs are cell surface peptidase, such as aminopeptidase N (APN) for HCoV-229E, dipeptidyl peptidase 4 (DPP4) for MERS-CoV, and angiotensin converting enzyme 2 (ACE2) for HCoV-NL63, SARS-CoV and SARS-CoV-2. On the other hand, HCoV-OC43 and HCoV-HKU1 employ glycan-based receptors carrying 9-O-acetylated sialic acid.

In addition to the receptor binding by the S protein, other HCoV structural proteins may also facilitate the early stage of attachment. For example, the M protein of HCoV-NL63 binds to target cells using heparan sulfate proteoglycans as the initial attachment factors. This is followed by the engagement of the S protein with the ACE2 receptor protein.

Viral Entry and Uncoating

Specific binding between S1 and the cognate receptor leads to a conformational change in the S2 subunit and large-scale rearrangements of the S protein, resulting in the fusion between virus and cell membranes and the release of viral nucleocapsid into the cytoplasm. Many host factors are involved in the entry and uncoating of HCoVs.

The cleavage of S protein into S1 and S2 subunits is mediated by one or more cellular proteases. HCoV-229E can enter host cells via two distinct pathways: one is mediated by surface proteases like type II transmembrane protease serine 2 (TMPRSS2), and another is mediated by endosomal cathepsin L. However, to avoid triggering an innate immune response, it is more likely that HCoV-229E enters cells via the TMPRSS2 pathway, as the endosome is a main site for recognition by toll-like receptors. Similarly, the entry of SARS-CoV depends on the endosomal cysteine protease cathepsin L and another trypsin-like serine protease to activate the S protein.

Coated vesicles and the cytoskeleton are utilized by some HCoV for entry. For example, HCoV-OC43 employs caveolin-1-dependent pathway of endocytosis, and the scission of virus-containing vesicles from the cell surface is dynamin-dependent. Internalization of these vesicles also requires rearrangements of the actin cytoskeleton. The interaction between HCoV-NL63 S protein and the ACE2 receptor molecule triggers the recruitment of clathrin. Subsequent vesicle scission by dynamin results in virus internalization, and the newly formed vesicle passes the actin cortex, which requires active cytoskeleton rearrangement.

Finally, acidification of the endosomal microenvironment is required for successful fusion and release of the viral genome into the cytoplasm. Additionally, virion release of HCoV-229E and IBV from early endosomes is shown to be dependent on the host factors valosin-containing protein (VCP), an AAA ATPase family protein that normally facilitates the export of misfolded proteins from the ER to the cytoplasm.

On the other hand, some host factors could prevent the entry and uncoating of HCoVs. Interferon inducible transmembrane proteins (IFITMs) exhibit broad-spectrum antiviral functions against various RNA viruses. IFITMs restricted the entry of HCoV-229E and HCoV-NL63, as well as SARS-CoV and MERS-CoV. Conversely, IFITM2 or IFITM3 serve as an entry factor to promote the infection of HCoV-OC43.

Formation of the Replication-Transcription Complex

Among RNA viruses, the transcription of coronavirus RNA is unique. First, in order to maintain genetic stability, the large genome size requires unusual enzymatic activities, such as an exoribonuclease and an endoribonuclease activity. Also, the synthesis of a nested set of sgRNAs by discontinuous transcription demands a huge and complicated RTC.

Following the release of viral nucleocapsid into the cytoplasm, the genomic RNA serves as a transcript encoding the viral replicase. The replicase gene includes two ORFs, ORF1a and ORF1b. ORF1a is translated into the polyprotein pp1a (440–500 kDa). Owing to a slippery sequence and an RNA pseudoknot near the end of ORF1a, a programmed –1 ribosomal frameshifting event can occur with a frequency of 25%–30%. This allows a continuous translation into ORF1b, producing a larger polyprotein pp1ab (740–810 kDa). Similar to likely all coronaviruses, the pp1a and pp1ab are autoproteolytically processed into 16 nsps, collectively forming the RTC for viral RNA synthesis. Notably, nsp3, 4, and 6 appear to be responsible for remodeling of cellular membranes to form DMVs or spherules, onto which the HCoV RTC is assembled and anchored. Host factors of the early secretory pathway, such as Golgi-specific brefeldin A-resistance guanine nucleotide exchange factor 1 (GBF1) and its effector ADP ribosylation factor 1, may also contribute to DMV formation and RTC assembly.

Viral RNA Synthesis

The assembly of RTC sets a foundation for viral RNA synthesis. By using the genomic RNA as a template, new copies of full-length viral genome are synthesized, using the full-length negative sense genomic RNA as the intermediate template. Meanwhile, the polymerase can switch templates at short motifs called transcription-regulated sequences (TRS) during negative sense RNA synthesis, producing a 5'-nested set of negative sense sgRNAs. These are in turn used as templates to synthesize a 3'-nested set of positive sense sgRNAs, which serve to encode the structural and accessory proteins. The core sequence of HCoV TRS is a conserved hexamer CUA AAC in HCoV-229E and HCoV-NL63, and a conserved heptamer UCU AAC in HCoV-OC43 and HCoV-HKU1.

Different numbers of sgRNAs are produced by the four common HCoVs. For instance, seven major viral RNA species are produced during HCoV-229E infection. The full-length genome (mRNA1) encodes the viral replicase, whereas mRNAs 2, 4, 5, 6, and 7 encode the S protein, accessory protein 4, E protein, M protein, and N protein, respectively. Notably, mRNA 3 is considered defective, because it contains a truncated version of the S gene that is not translated.

Although the replication and transcription of viral genome is mainly carried out by the replicase, the involvement of other factors including viral structural protein and host proteins has been implicated. For instance, by serving as an RNA chaperone, the coronavirus N protein can facilitate template switching during sgRNA synthesis. Host proteins such as heterogeneous

nuclear ribonucleoprotein A1, polypyrimidine tract-binding protein, mitochondrial aconitase, and polyadenylate-binding protein have been suggested to participate in coronavirus RNA synthesis, presumably mediated by their RNA binding activity.

Assembly and Release of Virion

Coronavirus structural and accessory proteins that are membrane-associated (such as S, HE, M, and E) are translated by ribosomes in the ER, whereas other viral proteins (such as N) are translated by free ribosomes. Most coronavirus structural proteins are also subjected to posttranslational modifications that modulate their functions. The building parts converge at the assembly site of ERGIC. Assembly is orchestrated by the M protein: homotypic interaction of M protein provides the scaffold for virion morphogenesis, whereas heterotypic interactions of M protein with other structural proteins, such as M-S and M-E, facilitate their recruitment and incorporation. Virion assembly is completed by the condensation of the nucleocapsid with the envelope components, a process mediated by M-N interactions. A small amount of E protein may provide the driving force for envelope morphogenesis by inducing membrane curvature.

After assembly, progeny virions are transported in smooth-wall vesicles, trafficked to the plasma membrane via the secretory pathway, and released by exocytosis. The cytoskeletal system also participates in HCoV assembly and release. For instance, the interaction between tubulin and the cytosolic domain of S protein are required for the assembly and release of infectious virions during HCoV-229E and HCoV-NL63 infection. In addition, bone marrow stromal antigen 2 (BST2, a.k.a. tetherin), an interferon-inducible antiviral protein, blocks the release of various envelope viruses by interfering with the budding step at the plasma membrane. Although budding of HCoV-229E occurs at the ERGIC, it is recently shown that BST2 can trap HCoV-229E virions in the intracellular vesicles, thereby suppressing the release of progeny viruses. Interestingly, the S protein of SARS-CoV downregulates BST2 at the protein level by promoting its lysosomal degradation, thus antagonizing the BST2 tethering of SARS-CoV, HCoV-229E, and HIV-1 virus-like particles.

HCoV-Host Interactions

As intracellular obligate parasites, HCoVs exploit the host cell machinery for their own replication and spread. Since virus–host interactions also form the basis of viral pathogenesis, knowledge about their interplay is of great research interest (Fig. 4).

Fig. 4 HCoV-host interaction. Schematic diagram showing the host signaling pathways activated during HCoV infection. Black pointed arrows indicate activation, and red blunt-ended lines indicate inhibition. Viral components modulating the pathway are in red, and host proteins are in blue. See text for detail.

Translational Control

Viruses must utilize the host translation machinery to ensure efficient viral protein translation. In response to acute viral infection, host cell would shut down the protein translation system to cope with the infection stress, which is regarded as an integrated stress response. Integrated stress response is marked by the phosphorylation of the α -subunit of eukaryotic initiation factor 2 (eIF2 α), downregulation of the general cap-dependent protein synthesis, and up-regulation of the expression of certain transcription factors, such as activating transcription factor 4 (ATF4). Due to the translation competition between cellular and viral mRNAs for limiting number of ribosomes and associated factors, coronavirus must hijack the host translational machinery to produce its own proteins.

Some HCoVs, such as SARS-CoV and MERS-CoV, have been shown to induce host translation shutoff in susceptible cells. Specifically, SARS-CoV infection leads to sustained phosphorylation of eIF2 α in 293T/ACE2 cells. Coronavirus nsp1 also suppresses host protein synthesis and IFN response. For example, SARS-CoV nsp1 suppresses the expression of host genes including type I IFN, thereby counteracts the host innate immune response and contributes to virulence. MERS-CoV nsp1 also negatively regulates host gene expression by inhibiting the translation and inducing the degradation of host mRNAs. Nsp1 of HCoV-229E and HCoV-NL63 inhibits the expression of reporter genes, probably by binding to ribosomal protein S6 and blocking the mRNA binding to the 40S ribosomal subunit.

ER Stress Response

The ER is a cellular organelle important for protein synthesis, folding, and post-translational modifications. In normal circumstances, the ER can be loaded with a very high concentration of proteins without perturbing its unique luminal environment. However, when the protein load exceeds the ER folding and processing capacity, misfolded or unfolded proteins will accumulate within the ER, resulting in ER stress. ER stress activates the signaling pathways collectively known as unfolded protein response (UPR). These are initiated by three ER transmembrane sensors: protein kinase R (PKR)-like ER kinase (PERK), inositol requiring enzyme 1 (IRE1) and activating transcriptional factor 6 (ATF6). The activation of UPR restores the ER homeostasis by enhancing protein folding, attenuating protein translation and ER-associated degradation (ERAD).

HCoV infection triggers ER stress and activates UPR in virus-infected cells. Overexpression of the S protein of HCoV-HKU1 and SARS-CoV can activate PERK and the promoters of GRP78 and GRP94. Infection with HCoV-OC43 activates IRE1 and induces X-box protein 1 (XBP1) mRNA splicing, thereby upregulating downstream UPR effector genes. Introduction of two point mutations (H183R and Y241H) into the S protein of HCoV-OC43 induces a higher degree of XBP1 mRNA splicing and results in a more pronounced apoptotic cell death. It is also reported that when the E gene is deleted from SARS-CoV, the mutant virus also induces a higher level of XBP1 mRNA splicing and apoptosis, compared with the wild type control. This suggests that activation of the IRE1-XBP1 pathway may be generally pro-apoptotic during HCoV infection.

MAP Kinase Pathway

The family members of the mitogen-activated protein (MAP) kinases mediate a wide variety of cellular processes in response to extracellular stimuli. Four distinct subgroups within the MAP kinase family have been described: extracellular signal-regulated kinase 1/2 (ERK1/2), ERK5, c-Jun N-terminal kinase (JNK), and the p38 group of protein kinases. Activation of the ERK pathway has been observed in cells infected with a number of HCoVs, including SARS-CoV, MERS-CoV, and HCoV-229E. Phosphorylation of the 90-kDa ribosomal protein S6 kinase (p90RSK), a key substrate of ERK, was also observed in SARS-CoV-infected Vero E6 cells. Activation of p38 and its upstream kinases has been detected in cells infected with HCoV-229E, SARS-CoV, and MERS-CoV. In fact, the replication of HCoV-229E is suppressed by treatment with p38 inhibitor SB203580 or chloroquine, which attenuates p38 activation. As for JNK, phosphorylation of JNK and its upstream kinases was observed in cells infected with SARS-CoV or in cells overexpressing the SARS-CoV S protein. Notably, treatment with JNK inhibitor abolished persistent infection of SARS-CoV. Apart from their involvement in cell survival and apoptosis, MAP kinases also contribute significantly to the induction of pro-inflammatory cytokines during HCoV infection.

Autophagy

Autophagy is a conserved cellular process involving self-eating. Specifically, cells under stress conditions, such as starvation, growth factor deprivation, or infection by pathogens, initiate autophagy in nucleation sites at the ER, where part of the cytoplasm and/or organelles are sequestered in DMVs (autophagosomes) and degraded in response to a fusion with lysosomes. Autophagy is regulated by highly conserved autophagy-related genes.

Coronavirus infection activates the formation of autophagosomes, but inhibition of autophagy does not affect viral replication. The non-structural protein 6 (nsp6) is a transmembrane protein implicated in the formation of DMVs during SARS-CoV infection. Overexpression of nsp6 of IBV, MHV, or SARS-CoV induced the formation of autophagosomes from the ER via an omegasome intermediate. However, autophagosomes induced by IBV infection or overexpression of coronavirus nsp6 had smaller diameters compared with those induced by starvation, indicating that nsp6 may also restrict the expansion of autophagosomes. Notably, recent studies have shown that coronavirus employs the host machinery for COPII-independent vesicular ER export to derive cellular membranes for DMV formation. Although this process requires an autophagy-related gene called LC3, it is independent of host autophagy.

Apoptosis

Apoptosis is a form of programmed cell death that is tightly regulated. When cells undergo apoptosis, they demonstrate specific hallmarks such as cell shrinkage, extensive plasma membrane blebbing, nuclear condensation, and DNA fragmentation. During viral infections, apoptosis is induced as one of the host antiviral responses to limit virus replication and production. Two main mechanisms of apoptosis have been established – the extrinsic and intrinsic pathways. The extrinsic pathway is initiated by the binding of extracellular death ligands to death receptors from the tumor necrosis factor super-family. The intrinsic pathway occurs internally in the cell and involves changes in the mitochondrial outer membrane permeability based on the ratio of pro-apoptotic and anti-apoptotic B-cell lymphoma 2 (Bcl2) family proteins.

As HCoVs are known to infect tissue cultures, they have been associated with apoptosis induction in a wide spectrum of cell types during infection, including intestinal mucosal cells, kidney tubular cells and neuronal cells. Apoptosis in neuronal cells infected with HCoV-OC43 involved mitochondrial translocation of Bcl-2-associated X protein (BAX) but this phenomenon was independent of caspase activation. HCoV-229E infection resulted in massive cytopathic effect (CPE) and cell death in dendritic cells, albeit independent of apoptosis induction. Since dendritic cells are prevalent throughout the human body, it is possible that they are used as a vehicle to facilitate viral spread. Induction of apoptosis during HCoV infection is also regulated by cellular stress response pathways such as the UPR and MAP kinase pathways described above.

Pathogenesis

HCoV-229E, -OC43, -NL63, and -HKU1 are considered as pathogens causing upper respiratory tract disease and responsible for up to 15%–30% of common colds in adults. Unlike SARS-CoV that spreads from the upper airway to cause a severe lower respiratory tract infection, HCoV-229E and HCoV-OC43 replicate principally in the upper respiratory tract epithelial cells, where they produce virus and cause local respiratory symptoms.

There are striking differences in the extent of genetic variability when isolates of HCoV-OC43 and HCoV-229E are compared. HCoV-229E isolated at geographically distinct locations shows little genetic variability, whereas for HCoV-OC43 the opposite is true. The ability of HCoV-OC43 to tolerate mutations probably accounts for its ability to grow in mouse cells and to infect the mouse brain as well. As for HCoV-NL63, it shares homology with HCoV-229E and phylogenetic analyses suggest that HCoV-NL63 and HCoV-229E diverged approximately 1000 years ago.

HCoVs attach to cellular receptors by the S protein on the surface of the virion. Internalization into host cells occurs by direct fusion with the plasma membrane or by endocytosis. Viral receptors, components that actively promote host cell entry, differ greatly from one virus to another, and each with its own distinct physiological functions. Both APN, the receptor for HCoV-229E, and ACE2, the receptor for SARS-CoV and HCoV-NL63, exist as prominent zinc-dependent peptidases on the plasma membrane. However, unlike SARS-CoV, HCoV-NL63 does not require cathepsin L or endosomal acidification to infect ACE2-expressing cells. In addition to the receptor ACE2, the entry of HCoV-NL63 also requires heparan sulfate proteoglycans on the cell surface, which act as attachment factors that increase the virus density and possibly facilitate receptor binding. Proteolytic cleavage of the HCoV S protein is also an important regulatory mechanism. In recent studies, the proteolytic activation of the HCoV-229E S protein is analyzed using trypsin-like serine proteases. It is found that fusion activation is not dependent on the cleavage of the S1/S2 site, but is highly dependent on the cleavage in the S2' region. This is very similar to the fusion activation of the IBV S protein, which requires furin-dependent cleavage at the S2' site.

Compared with SARS-CoV and MERS-CoV, the ability of other HCoVs causing mild infections to suppress the host antiviral response is less well studied. HCoV-229E replication is shown to attenuate the inducible activity of the transcription factor nuclear factor kappa-B (NF- κ B) and to restrict the nuclear accumulation of NF- κ B subunits. Overexpression of structural or accessory proteins of HCoV-OC43 also leads to downregulation of over 30 genes related to innate immune response, including genes encoding MAP kinases, toll-like receptors, interferons, interleukins, and signal transduction proteins. Similar to the PLPro of SARS-CoV and MERS-CoV, the PLP2 of HCoV-NL63 possesses deubiquitinating (DUB) activity. This DUB activity may remove ubiquitins from critical intermediates in the innate immune signaling pathway, thereby suppressing host antiviral response. PLPro of SARS-CoV and MERS-CoV also recognizes and catalyzes the removal of another ubiquitin-like modifier called interferon-stimulated gene 15 (ISG15). Such deISGylating activity has not been fully characterized for other HCoVs.

HCoV infection is not always confined to the upper respiratory tract and can invade the central nervous system (CNS) under circumstances that are presently uncharacterized. Although evidence for a significant correlation between the presence of HCoV-229E and HCoV-OC43 RNA and multiple sclerosis has not been demonstrated, accumulating evidence from cell culture and animal models highlights their neurotropic and neuroinvasive potential. HCoV-229E RNA is detected in about 44% (40 of 90) of human brains tested, with similar frequencies in brains from multiple sclerosis patients and patients who died from other neurologic diseases or normal control subjects. The detection of HCoV RNA in human brain samples clearly demonstrates that these respiratory pathogens are naturally neuroinvasive in humans and suggests that they may establish a persistent infection in the human CNS. Therefore, the close structural and biological relatedness of HCoV to the neurotropic animal coronaviruses has led to speculation of the possible involvement of HCoV in neurological diseases. Research proved that classical apoptosis associated with the BAX protein does not play a significant role in HCoV-OC43-induced neuronal cell death and that RIP1 and MLKL, two cellular proteins that are usually associated with necroptosis, another form of regulated cell death when apoptosis is

not adequately induced. It is likely that in HCoV-OC43-infected neuronal cells, RIP1 and MLKL are activated to induce necroptotic cell death in an attempt to limit viral replication. However, this regulated cell death also leads to neuronal loss in the mouse CNS and accelerates the neuroinflammation process, reflecting the severity of neuropathogenesis.

Epidemiology and Clinical features

HCoV-229E, -OC43, -NL63, and -HKU1 are distributed globally. By spreading via coughing and sneezing, they cause mild upper respiratory tract diseases in adults. However, in infants, young children, elderly, and immunocompromised individuals, they may sometimes cause life-threatening bronchiolitis and pneumonia. Apart from respiratory illnesses, they may also result in enteric and neurological diseases. Natural infection is probably acquired in a fashion similar to that of many other respiratory viruses, with primary infection of ciliated epithelial cells in the nasopharynx. Although HCoVs were found to cause epidemics every 2–3 years with a high probability of reinfections, there is a paucity of evidence on the epidemiology and clinical manifestations of these four HCoVs worldwide. Reinfection of HCoVs demonstrates that infection does not induce long-lasting protective immunity.

HCoV-229E

First isolated in 1966, HCoV-229E is proposed to originate from African hipposiderid bats and adopt camelids as intermediate hosts. The evolutionary history of HCoV-229E likely shares important characteristics with that of the recently emerged highly pathogenic MERS-CoV. HCoV-229E infection is associated with common cold symptoms in healthy adults. But younger children and the elderly are vulnerable to lower respiratory tract infections. In particular, immunocompromised patients have been reported to suffer severe and life-threatening lower respiratory tract infections attributed to HCoV-229E. Moreover, the serological test suggested the possible involvement of HCoV-229E in the development of Kawasaki syndrome.

The incubation period of HCoV-229E is approximately 2–5 days, followed by illness lasting 2–18 days. Symptoms of HCoV-229E infection include headache, nasal discharge, sneezing, sore throat and general malaise. A few patients exhibit fever and cough. The clinical features can be distinguished from respiratory tract infections caused by other pathogens such as influenza A virus. HCoV-229E tends to be epidemic during winter in temperate-climate countries, and tests of a HCoV-229E laboratory strain suggested it is relatively stable in the environment.

HCoV-OC43

First isolated in 1967, HCoV-OC43 has no serological cross-reactivity with HCoV-229E. However, patients infected with HCoV-OC43 or HCoV-229E cannot be distinguished based on clinical symptoms alone; although coryza (inflammation of the mucous membrane of the nose) occurs more often during HCoV-229E infections, while sore throat manifestations occur more often during HCoV-OC43 infections.

HCoV-OC43 is generally associated with mild upper respiratory tract infections, although it has also been shown to have neuroinvasive properties. In vivo studies in mice have shown that HCoV-OC43 can infect neurons and cause encephalitis. The virus has also been shown to cause persistent infections in human neural cell lines. Since the first isolation of HCoV-OC43 in the 1960s, seven genotypes (A–G) have been identified by phylogenetic analysis. HCoV-OC43 is also transmitted primarily during the winter in temperate climates.

HCoV-NL63

HCoV-NL63 was isolated from a 7-month-old girl with coryza, conjunctivitis, fever, and bronchiolitis in the Netherlands in 2004. HCoV-NL63 and HCoV-OC43 cause most of the respiratory infections leading to hospitalization. Although HCoV-NL63 infections often exists in mixed viral infections, the mixed infection does not usually increase the severity of the disease. In about 71% of the cases, patients are co-infected with other respiratory viruses, such as human rhinovirus, enterovirus and parainfluenza viruses. In most patients, HCoV-NL63 infection is associated with relatively mild symptoms like fever, cough, sore throat and rhinitis. Furthermore, HCoV-NL63 is one of the main causes of croup in children.

HCoV-NL63 infects people in all ages, with the highest infection rate occurring before 5 years of age. It is estimated that 1%–10% of the population suffers annually from cold-like symptoms related to infection with HCoV-NL63. HCoV-NL63 epidemic shows a peak during the spring and summer in Hong Kong, indicating that the seasonality of HCoV-NL63 infection may not be restricted to the winter in tropical and subtropical regions. Surprisingly, studies show that HCoV-NL63 virions are exquisitely stable in liquid media and can be stored also without preservatives at ambient temperature for up to 14 days.

HCoV-HKU1

HCoV-HKU1 was isolated from an adult who had a chronic pulmonary disease in Hong Kong. The clinical symptoms of HCoV-HKU1 infection included rhinorrhea, cough, nasal congestion, fever, sputum, sore throat, chills, postnasal discharge, and tonsillar hypertrophy. About 50% of patients infected with HCoV-HKU1 experience febrile seizures, but the symptoms of HCoV-HKU1 infections in the respiratory tract are not easily separable from those caused by other respiratory viruses. HCoV-HKU1 co-circulates with respiratory syncytial virus and an epidemic usually appears prior to influenza season. In addition, HCoVs have been associated with wheezing and exacerbations of asthma.

Similar to other three mild disease causing HCoVs, HCoV-HKU1 is distributed worldwide. HCoV-HKU1 infection is relatively frequent in adults. One recent study has examined the circulation of HCoV in Israel during 2015–2016. In the winter influenza survey, 10.36% of patients were infected with the other three common HCoVs; among them, 43.43% were infected with HCoV-OC43, 44.95% with HCoV-NL63, and 11.62% with HCoV-229E. Although it is absent from the winter survey, 22.6% of the hospitalized patients were positive for HCoV-HKU1, mainly during the spring-summer period.

Diagnosis

In most cases, HCoV infections, other than SARS-CoV or MERS-CoV, are not well identified by clinical diagnosis because they cause mild, upper respiratory tract disease, and no specific therapy is available. At the same time, HCoV detection is carried out in a limited number of virological laboratories, because HCoV infections cannot be easily distinguished clinically from other causes of upper respiratory tract infections. The presence of multiple genotypes and the co-infection with other respiratory viruses, such as human rhinoviruses, enteroviruses and parainfluenza viruses, render the detection of HCoV even more challenging. HCoVs are also sometimes detected in asymptomatic patients/individuals; so that the presence of these viruses may not be etiologically related to the illness.

Electron microscopic examination of the clinical materials, although laborious, has contributed to the identification and characterization of many HCoVs. Electron microscopy has been extensively used in most of the initial studies, also because isolation of HCoVs from infected individuals and their propagation in tissue culture cells have been technically challenging. HCoV-229E has sometimes been isolated in human diploid cell lines. However, HCoV-OC43 initially required cell organ culture systems for isolation, although this virus can now be grown in tissue culture cells. HCoV-NL63 can infect monkey kidney LLC-MK2 cells or Vero cells, whereas HCoV-HKU1 has been grown only in primary human airway epithelial cells. Sometimes, these cell or organ culture techniques are labor intensive, time consuming, and relatively insensitive.

HCoVs can be detected by RT-PCR with greater sensitivity than standard culture techniques. Nasopharyngeal aspirates are the most common respiratory samples for diagnosis. PCR primers can be designed to be broadly reactive or strain specific, based on primer binding sites (usually in the viral replicase and/or the N gene). A multiplex real-time RT-PCR assay capable of detecting all four common HCoVs (HCoV-229E, OC43, NL63 and HKU1) has become the diagnostic method of choice. A simple and sensitive assay for rapid detection of human coronavirus NL63 (HCoV-NL63) has been developed by colorimetric reverse transcription loop-mediated isothermal amplification (RT-LAMP). This method employs six specially designed primers that recognize eight distinct regions of the HCoV-NL63 nucleocapsid protein gene for amplification of target sequences under isothermal conditions at 63°C for 1 h. This RT-LAMP assay can achieve a high sensitivity of 1600 RNA copies per reaction with high specificity, and is suitable for clinical settings without conventional PCR equipment.

Various serologic assays can also be used to detect HCoV infections, including complement fixation assays, neutralization assays, immunofluorescence assays (IFA), enzyme-linked immunoassays (EIA), and hemagglutination inhibition (HI) for viruses with an HE protein. Monoclonal antibodies have also been generated for direct detection of HCoV antigens in nasopharyngeal aspirates samples. Complement-fixing and enzyme-linked immunosorbent assays (ELISA) for HCoV-229E and HCoV-OC43 have been published, but are not yet available in clinical laboratories.

Serologic tests for specific antibody responses against HCoVs are mainly reserved for epidemiologic studies. Initially, virus lysates or inactivated whole viruses were used as antigens for serologic assays. More recently, cloned expressed proteins, synthesized peptides, and pseudoviruses are also used. For example, recombinant N protein of HCoV-HKU1 expressed by *E. coli* and baculovirus has been used for IgG and IgM detection of sera from patients and normal individuals, using Western blot and EIA.

Treatment

At present, there are no specific antiviral drugs available for treating HCoV infections, and therapy is therefore primarily supportive. Studies have shown that, if diagnosed early, HCoV-NL63 replication can be suppressed by treatment with PEG-IFN. The effect of various chemicals to inhibit HCoV replication has been studied in cell culture. Potential targets for anti-HCoV drugs include inhibiting virus entry, viral RdRP, and viral protease such as Mpro.

Similar to SARS-CoV and MERS-CoV, peptide-based membrane fusion inhibitors targeting the heptad repeat 1 (HR1) and HR2 of HCoV-229E S protein have been developed. They effectively inhibit S-mediated membrane fusion and the replication of

HCoV-229E in cell culture. Moreover, when administered intranasally to a mouse model, these inhibitors could widely distribute in the upper and lower respiratory tracts and maintain fusion-inhibitory activity. Some polymers, such as a cationically modified chitosan known as N-(2-hydroxypropyl)-3-trimethylammonium chitosan chloride and its derivatives, have been shown to block HCoV-NL63 entry by inhibiting the receptor binding of S protein. Viral entry can also be inhibited using serine proteases (such as camostat) and cysteine protease inhibitor (such as K11777). These compounds inhibit the critical proteolytic activation of HCoV S protein, thereby blocking the entry step of HCoV infection. Chloroquine, a compound that inhibits acidification of endosomes, can also strongly inhibit the replication of HCoV-OC43 in vitro.

The nucleoside analog ribavirin has been used to treat RSV infection, hepatitis C, and some viral hemorrhagic fevers. However, ribavirin only shows inhibition of HCoV-OC43 replication in cell culture at high concentrations ($IC_{50} \sim 10 \mu M$), which may not be applicable to humans in clinical treatment. Remdesivir (GS-5734) is a novel adenosine analog prodrug. By targeting the viral RdRP, remdesivir exhibits potent antiviral activity against HCoV-OC43 and HCoV-229E with submicromolar IC_{50} values in cell culture.

Targeting host factors required for replication may be another viable therapeutic approach against HCoV infection. A systemic investigation of HCoV-host interactome has identified cyclophilins as targets for pan-coronavirus inhibitors. In fact, knockdown of cyclophilin A (CypA) in Caco-2 cells inhibits the replication of HCoV-NL63, suggesting that CypA is required for virus replication. Notably, when cells are treated with cyclosporinA (CsA) or FK506, potent immunosuppressive drugs that bind to CypA or related immunophilins, the replication of HCoV-NL63, HCoV-229E, and SARS-CoV is inhibited. Importantly, recent studies also show that CsD Alisporivir, NIM811, and other novel non-immunosuppressive derivatives of CsA and FK506 can also strongly inhibit the growth of HCoV-NL63 in cell culture at low micromolar, non-cytotoxic concentrations. Therefore, non-immunosuppressive CypA inhibitors may be promising candidates as antivirals against HCoV infection. Interestingly, the replication of HCoV-229E and MERS-CoV is also suppressed when exogenous arachidonic acid or linoleic acid is added to the culture medium, suggesting that the regulation of host lipid metabolism could also be a common and druggable target for coronavirus infections.

Prevention

Due to the mild diseases associated with the infection by the four common HCoVs, no vaccines are currently available or being developed. Risk of infection can be reduced by good hand hygiene and coughing etiquette and avoiding close contact with infected individuals.

Human Cytomegalovirus (*Herpesviridae*)

Edward S Mocarski, Emory University School of Medicine, Atlanta, GA, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

allogeneic MHC-mismatched cell, tissue or organ.

allograft A tissue or organ from someone other than an identical twin.

alphaherpesvirus A subfamily of herpesviruses characterized by epithelial infection with latency in sensory neurons.

antibody Secreted protein, called immunoglobulin, made by immune system plasma cells that protect by recognizing a specific antigen such as on the surface of viruses.

antigen a specific pathogen component recognized by antibody, B cell receptor or T cell receptor.

betaherpesvirus A subfamily of herpesviruses that includes the cytomegaloviruses and closely related salivary gland viruses.

capsid The protein shell part of a virion into which viral DNA is packaged.

capsomer A subunit of the capsid, also called a protomer.

cleavage/packaging A process of inserting viral DNA into a capsid and cutting viral DNA during nucleocapsid maturation.

concatemer A long repetitive head-to-tail structure, applied to replicating viral DNA prior to cleavage/packaging.

congenital Evident at birth.

core gene A subset of evolutionarily conserved common herpesvirus genes that carry out entry, replication, virion formation and maturation.

cytopathology An alteration in appearance of cells, typically during infection.

dense body A capsidless particle composed of tegument surrounded by an envelope.

differentiation state-dependent A process that only occurs in cells at a particular point in their developmental or somatic differentiation.

DNA A type of nucleic acid that encodes genes and forms the genome of some viruses and all organisms.

early gene A gene expressed prior to the initiation of viral DNA replication.

egress A process during viral maturation where the virion leaves the cell.

encapsidation The process of packaging viral DNA into nucleocapsids.

envelope A lipid bilayer membrane that surrounds the tegument of virions and dense bodies that contains viral glycoproteins responsible for binding to and entering into cells.

envelopment The process of adding an envelope to nucleocapsid.

epigenetic non-heritable.

ERGIC Endoplasmic reticulum-Golgi intermediate compartment, the cellular site of envelopment.

gammaherpesvirus A subfamily of herpesviruses characterized by oral transmission, oncogenicity and latency in lymphocytes.

genome The nucleic acid molecule that encodes all of the genes of a virus or an organism.

helicase-primase A replication enzyme that unwinds nucleic acid and synthesizes short primers that are extended by DNA polymerase.

hematopoietic Blood-forming.

herpesvirus A virus family characterized by a large DNA genome, similar-appearing enveloped virion particle and lifelong latency.

hexon A type of capsomere/protomer forming most of the capsid structure.

homologous gene products Proteins with evolutionary relatedness.

immediate early gene The first set of genes expressed during infection.

immunity Resistance to infection and disease through natural (innate) or acquired (adaptive) host defense mechanisms

immunocompetent Having the capacity for immunity.

immunocompromised Lacking the capacity for immunity.

immunodeficiency An inborn or acquired lack of immunity.

immunosuppression A reduction in immunity.

inapparent Lacking in signs or symptoms.

infectious Capable of person-to-person transmission (transmissible).

late gene The last set of genes expressed during infection.

latency Persistence in the absence of active replication with the potential to reactivate.

leukodepletion Reducing the leukocytes.

major histocompatibility complex (MHC) Tissue antigens that present antigen to T cells that vary in the population such that no two people are alike (except for identical twins).

monoclonal antibody Antibody produced by a single B cell or plasma cell recognizing a specific antigen.

mononucleosis The proliferation of mononuclear leukocytes (lymphocytes).

neurodevelopmental Related to the development of the nervous system.

nucleocapsid A DNA-containing capsid.

opportunistic A pathogen that infects and causes disease in immunocompromised hosts.

opportunistic pathogen Causing disease the immunocompromised host.

pathogen A disease-causing virus, microbe or multicellular organism.

pathogenesis	The process of causing disease.	seronegative	Lacking pathogen-specific antibody.
penton	A type of capsomere that composes capsid vertices.	seropositive	Having pathogen-specific antibody.
persistence	The act of remaining.	seroprevalence	Proportion of seropositive individuals in a population.
plaque forming unit	A single infectious virus as determined by plaque assay.	tegument	The layer of protein between the capsid and envelope in a virion.
portal	An entrance.	transfusion	The transfer of blood from one person to another.
promoter	A segment of DNA that directs transcription of a gene.	transplacental	Crossing the maternal-fetal interface during pregnancy.
reactivation	The process of transitioning from latency to active replication.	transplant	The transfer of a tissue or organ from one individual to another.
reinfection	The act of becoming infected with the same pathogen again.	tropism	The likelihood of a particular tissue or cell to support virus replication.
replication	The process of making more viral DNA and virus.	viral assembly compartment	A cytoplasmic location where virus assembly and release takes place.
restriction factor	A gene product that slows down or blocks a pathogen.	virion	A assembled, infectious virus particle, typically observed outside of a host cell.
roseolavirus	A subset of betaherpesviruses that includes HHV-6A, HHV-6B and HHV-7.		
sequence identity	Having similar nucleic acid (DNA or RNA) or amino acid (protein) order.		

Classification

Cytomegaloviruses (CMVs) are defining members of the betaherpesviruses, one of the major subfamilies of herpesviruses infecting mammalian hosts. Herpesviruses are a biologically diverse, ancient group of viruses that are characterized by large DNA genomes (from just over 100,000 kilobase pairs to nearly 300,000 kilobase pairs), as well as a common virion structure, replication scheme and the biological property of lifelong latency. Betaherpesviruses generally, and CMVs in particular are more highly host restricted than other herpesviruses. CMVs were initially referred to as salivary gland viruses because they are sporadically shed into saliva which, along with urine and breast milk, represent primary sources for transmission. Although restricted to a single host species in nature, all CMVs share a common ancestor, biological features and characteristic cytopathology that includes a nuclear site of replication and a cytoplasmic assembly compartment where final envelopment and egress occur (**Fig. 1**). Despite species specificity, amino acid sequence similarity in proteins provides molecular evidence supporting the biological relatedness of betaherpesviruses that infect various animal species (**Fig. 2**). The cytomegalovirus (CMV) of humans (HCMV), officially classified *Human herpesvirus* (HHV)5 within the genus *Cytomegalovirus*, subfamily *Betaherpesvirinae* of the family *Herpesviridae*, has the largest and most complex genome of any human herpesvirus with a potential to encode hundreds of gene products. The other human betaherpesviruses, roseolaviruses classified as HHV6A, HHV-6B and HHV-7 have smaller genomes and retain homologs of approximately half of the canonical, annotated HCMV genes (shaded genes in **Table 1**). Betaherpesviruses of mice, rats, guinea pigs and monkeys are all species-restricted viruses that are more similar to HCMV than to roseolaviruses. Because they naturally infect laboratory animals, all have been used to model aspects of HCMV infection, immunity, latency and pathogenesis. Mammalian betaherpesviruses replicate slowly in cultured cells which must be from their natural host species, remain cell-associated within the host, and show genetic relatedness to each other more so than they do to either alphaherpesviruses or gammaherpesviruses.

Virion Structure

Virions of HCMV appear similar to other herpesviruses (**Fig. 1**) despite a larger genome and a more complex coding capacity. The ~230 nm enveloped virion includes a linear double-stranded DNA genome tightly packed within a 130 nm icosahedral nucleocapsid surrounded by a tegument layer with ~30 virus-encoded phosphoproteins surrounded by a lipid bilayer envelope containing ~22 viral membrane glycoproteins (**Table 1**). The most abundant tegument constituents are phosphoprotein (pp)65 (ppUL83) and pp150 (ppUL32). Although the most structurally complex of any characterized herpesvirus, the HCMV capsid is composed of herpesvirus-conserved major capsid protein (MCP), the primary constituent of capsomers (both hexons and pentons), as well as minor capsid proteins that form intercapsomeric triplexes, the smallest capsid protein (SCP) that decorates the hexon tips, and the portal protein (PORT) comprising one penton position responsible for conducting viral DNA encapsidation. In addition to a linear molecule of DNA, RNA associates with the origin of lytic DNA replication (*oriLyt*) in virions. The most biologically important HCMV envelope constituents are glycoprotein (g)B and complexes composed of gH:gL:gO (gH/gL trimer), gH:gL:pUL128:pUL130:pUL131A (gH/gL pentamer) and gM:gN which all play crucial roles in replication. Envelope gB and gH:gL complexes are very important targets of host humoral (antibody) immunity. Numerous additional envelope glycoproteins

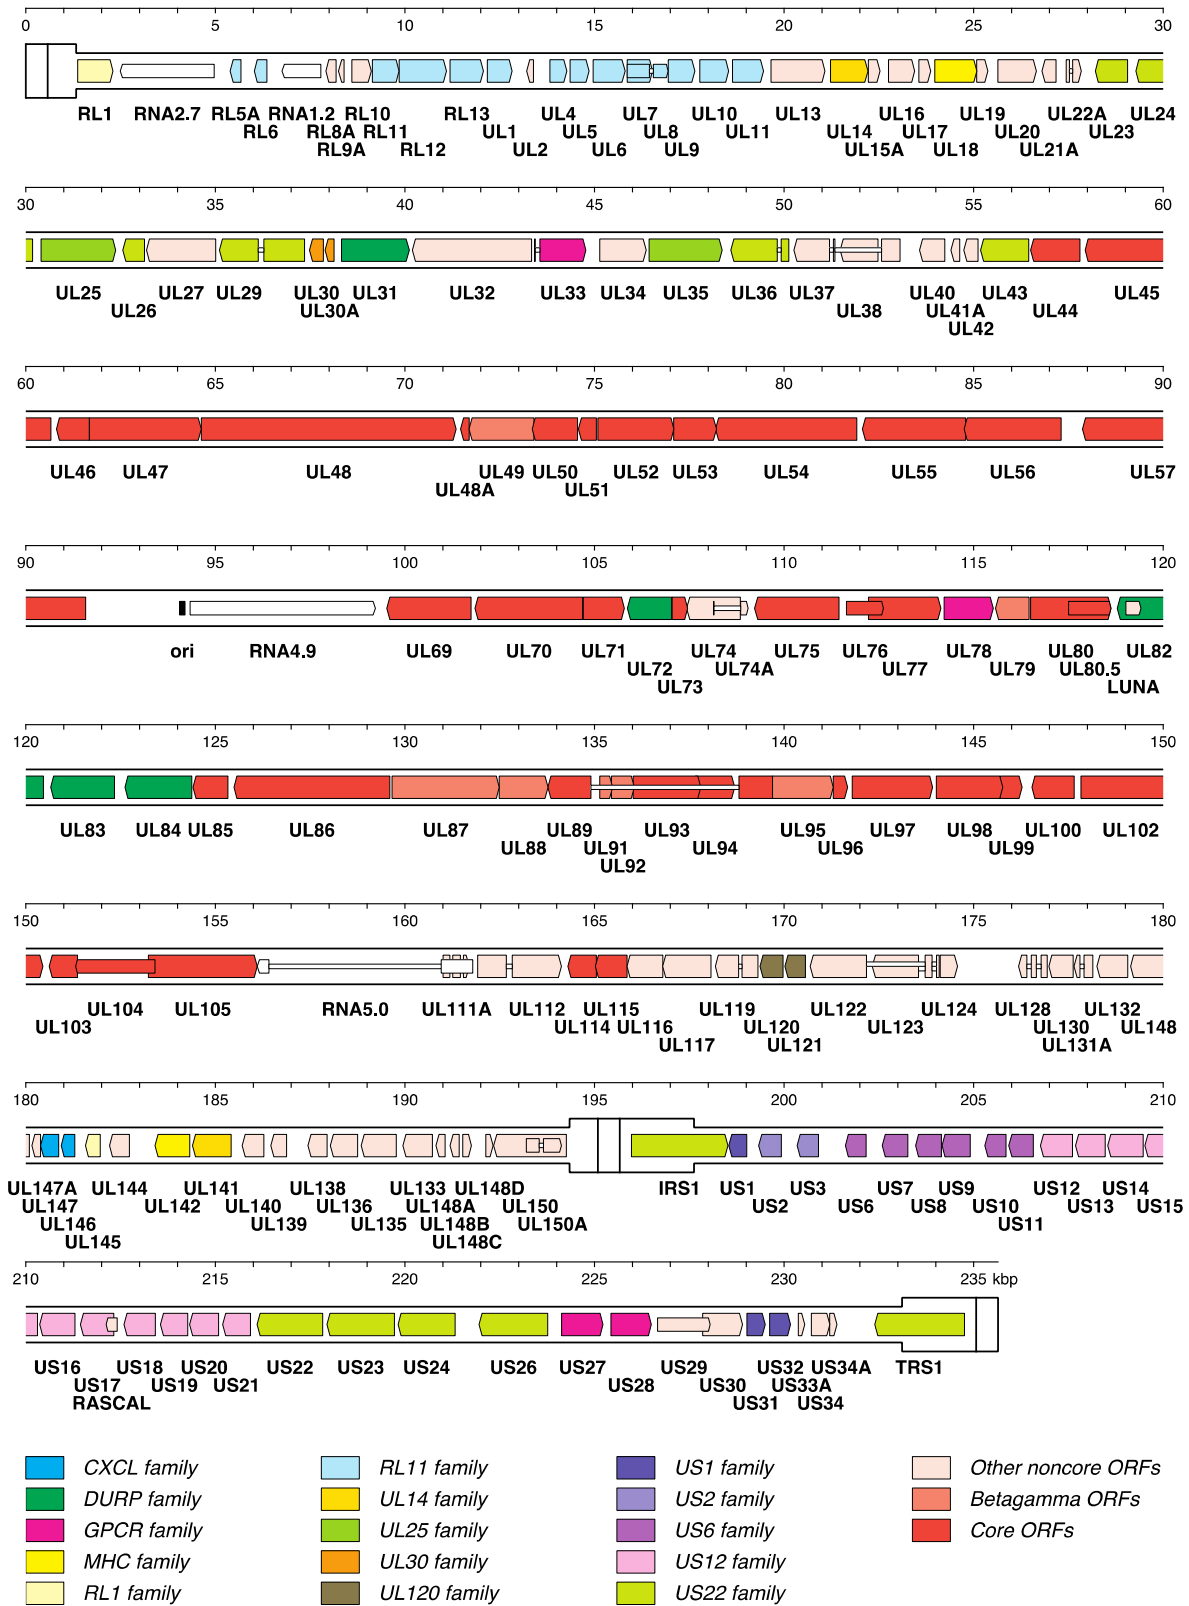

Fig. 1 Cryo and transmission electron micrograph (EM) of HCMV particles and HCMV-infected human fibroblast cells. A. Cryo-EM virion particle structure (strain AD169) showing the nucleocapsid, tegument and envelope with embedded gB (but without gH: gL pentamer) after sedimentation (note distortion of the envelope). B. Cryo-EM nucleocapsid particle from within a virion showing capsomeres and appearance of encapsidated viral DNA. C. Transmission EM of HCMV infection (multiplicity of infection = 3) at day five postinfection showing a cell with nucleus and mature virions and dense bodies within the cytoplasmic assembly compartment where final envelopment precedes release by exocytosis through the plasma membrane to the extracellular space. Released mature extracellular virus particles accumulate between adjacent cells of the monolayer. Inset shows a close-up of mature virions (arrows) and dense bodies (arrow heads) within the assembly compartment. Intracellular virus particles are contained within vesicles. Panels A and B courtesy of Hong Zhou, UCLA.

(Table 1) are dispensable for replication in cultured cells although each likely contributes to virus biology in the host by influencing cell tropism, tempering host response to infection and dictating pathogenesis as well as persistence. Capsidless particles (called dense bodies), composed solely of tegument surrounded by an envelope, are produced in numbers equivalent to virions during infection (Fig. 1). Dense bodies as well as noninfectious capsid-containing particles predominate in all virus preparations, such that particle-to-plaque forming unit (PFU) ratios of HCMV stocks range from a low of 100:1 to over 1000:1.

Genome

Structure

The HCMV genome is a single ~236,000 bp double-stranded DNA molecule composed of unique long (U_L) and unique short (U_S) regions flanked by terminal and internal repeats in an arrangement depicted $ab-U_L-b'a'c'-U_S-ca$ (alternative depiction,

TRL-UL-IRL-IRS-US-TRS). This structure is similar to human herpes simplex viruses but, with the exception of chimpanzee CMV, is not observed with nonhuman CMVs. Because recombination occurs between the inverted repeats of these herpesvirus genomes, virus particles carry one of four different sequence arrangements, or isomers, that are all infectious. The genome depicted in **Fig. 2** includes conventional annotated and canonical protein-coding genes, four long noncoding (lnc) RNA genes and an origin of replicative DNA synthesis (*oriLyt*) located between UL57 and UL69, cleavage/packaging signals (*pac1* and *pac2* within terminal *a* sequences) and the major immediate early (IE) promoter (MIEP), a transcriptional enhancer that controls transcription of IE1 (p72) and IE2 (p86) genes (located between UL124 and UL128). The genome also encodes 23 micro (mi)RNA genes not depicted in **Table 1** or **Fig. 2**. Importantly, HCMV is known to encode many more than the ~200 annotated gene products shown in such conventional depictions. Hundreds of additional candidate viral proteins have been detected experimentally. The genome organization of human roseolaviruses (HHV6A, HHV6B and HHV7) as well as other nonhuman CMVs are co-linear with the HCMV genome, although their smaller genomes (145,000–162,000 base pairs) encode only ~85 proteins where ~70 genes are colinear with HCMV, from UL23 to UL124 (shaded rows in **Table 1**). Despite these evolutionarily conserved gene products, human roseolaviruses and HCMV do not exhibit significant DNA sequence identity. All characterized betaherpesvirus genomes also have a similarly positioned *oriLyt*, MIEP-enhancer and terminal direct repeats with conserved genome-terminal cleavage/packaging signals.

Evolution

Based on the similarity to HCMV gene products and genome organization, CMVs have been estimated to have coevolved with common ancestors of mammals over the past 150 million years. The core genes that mediate the herpesvirus-conserved processes of viral DNA synthesis, capsid assembly and genome cleavage/packaging (nuclear events shown in **Fig. 3**), as well as a set of genes involved in transcription of true-late gene products, including a viral TATA binding protein (**Table 1**), likely have their evolutionary origin in a distant DNA bacteriophage ancestor. These and virion maturation events from nuclear egress through final envelopment and release require the function of herpesvirus core genes (**Table 1** and **Fig. 3**). Because of their long evolution, betaherpesviruses exhibit a greater level of divergence than their respective host species. As such, non-human primate CMVs exhibit diversity in gene content and function evident even when comparing great ape and human CMVs. This extreme diversity in biologically related, but species-specific viruses is much greater than observed in alphaherpesviruses or gammaherpesviruses. The greatest conservation in genome organization is between viruses infecting closely related host species such as HCMV and chimpanzee CMV or murine CMV and rat CMV. There even appears to be a level of diversity generated during lifelong infection with HCMV, above and beyond the presence of multiple strains in a single host. Complete genome sequences have been determined for many circulating HCMV strains, including those that have been detected directly in secretions or infected tissues. An average of >95% DNA sequence identity is observed between HCMV strains. A similar range of viral strains appear to circulate worldwide. The presence of multiple strains and within-host variation as well as the detection of multiple distinct strains within a single individual are all features that may influence disease pathogenesis but most certainly document susceptibility to reinfection. Thus, in every animal species that has its own CMV, the virus enjoys both a widespread distribution and the ability to superinfect.

Life Cycle

HCMV, and related mammalian viruses, cause systemic infection primarily targeting myelomonocytic, epithelial and endothelial cells. Like other herpesviruses, HCMV establishes chronic/persistent infection characterized by lifelong latency. Only a minor proportion of viral genes, mostly betaherpesvirus-common and herpesvirus core proteins, carry out DNA replication and cleavage/packaging as well as virion assembly, maturation and release (**Table 1**). A majority of cytomegalovirus gene products modulate host defense mechanisms, acting within an infected cell (cell autonomous) as well as systemically to alter the course of innate and adaptive immunity, subverting some pathways and enhancing others (see Pathogenesis section). CMVs target conserved host defense pathways, evidence that these master manipulators co-evolved during the radiation of mammalian species as immune mechanisms were acquired.

Host Range

HCMV only infects humans. There are no known susceptible nonhuman hosts, in nature or under experimental conditions. Furthermore, cultured human epithelial, endothelial, neuronal, myeloid and fibroblast cells are all susceptible. Chimpanzee

Fig. 2 Genetic organization and annotated gene content of wild-type HCMV, based on low passage strain Merlin. The 236 kbp HCMV genome is depicted on eight lines with each gene arranged by orientation. Inverted repeats TRL/IRL (*ab-b'a'*) and TRS/IRS (*a'c'-ca*) are shown in a thicker format than the UL₁ and US₁ components. Protein-coding regions (ORFs) are indicated by large colored arrows grouped according to the key shown at the bottom. 15 different gene families, core ORFs conserved across all mammalian and avian herpesviruses, betagamma ORFs conserved only in betaherpesviruses and gammaherpesviruses and other non-core ORFs are each depicted by a separate color. Noncoding RNAs are indicated by medium, white arrows (micro RNAs are not shown). Introns are shown as narrow white bars. Gene nomenclature is shown below the genome depiction. UL72 is both a core ORF and a member of the DURP gene family. Reproduced by permission of the Society for General Microbiology; modified by A. Davison.

Table 1 Annotated cytomegalovirus gene products: Characteristics and functions

HCMV ^{a,b}	Kinetic Class, Gene Family (Characteristics) ^c	Function (Comments) Gene Product Name ^d
RL1	LL <i>RL1</i>	
lncRNA2.7	E (most abundant noncoding RNA)	Binds mitochondrial complex I (↓ cell death) β2.7
RL5A	LL <i>RL11</i> (membrane-like gp)	
RL6	LL <i>RL11</i> (membrane-like gp)	
lncRNA1.2	E (abundant noncoding RNA)	
RL8A	LL (multiply spliced)	
RL9A	LL	
RL10	LL (envelope gp)	
RL11	LL <i>RL11</i> (envelope gp, modulation)	Binds IgG Fc (↓ NK-mediated ADCC) gp34/gpRL11
RL12	LL <i>RL11</i> (membrane gp, modulation)	IgG Fc-binding (antibody decoy) gp95/gpRL12
RL13* [#]	LL <i>RL11</i> (envelope gp, modulation)	NUDT14-binding protein (drives host restriction but allows spread in the presence of HCMV-specific antibody) gpRL13
UL1	TL <i>RL11</i> (envelope gp, modulation)	(Cell tropism determinant) gpUL1
UL2	LL (membrane gp)	
UL3	(modulation)	Disrupts nuclear PML and Cajal bodies (↓ IFN response) pUL3
UL4	E & TL <i>RL11</i> (envelope gp)	(Expression regulated by translational stalling at uORF2) gp48/gpUL4
UL5	E <i>RL11</i> (envelope gp)	gpUL5
UL6	LL <i>RL11</i> (membrane-like gp)	gpUL6
UL7	LL <i>RL11</i> (membrane gp; CD229/SLAM homolog, modulation)	Activates FLT3R (↓ inflammatory cytokine production; ↓ myeloid cell differentiation) gpUL7
UL8	LL <i>RL11</i> (CD229/SLAM homolog, modulation)	(↓ cytokine production, contains UL7-common exon) gpUL8
UL9*	LL <i>RL11</i> (membrane gp)	(↓ replication in fibroblasts)
UL10*	LL <i>RL11</i> (membrane gp)	(↓ replication and cytokine production in fibroblasts)
UL11	LL <i>RL11</i> (membrane gp, modulation)	Activates CD45, driving IL-10 (↓ T cell activation) gpUL11
UL13	IE (secreted gp)	
UL14	E <i>UL14</i> (membrane gp)	
UL15A	E (membrane-like gp)	
UL16*	E (membrane gp, modulation)	Sequesters NKG2D ligands (↓ NK cell killing) gpUL16
UL17	LL (membrane gp)	gpUL17
UL18	LL <i>UL18</i> (MHC1 homolog, modulation)	Binds LIR-1 (↓ NK activation, requires gpUL40) gpUL18
UL19	LL	
UL20	E (TCR γ chain homolog)	
UL21A*	E (regulation)	Destabilizes cyclin A (↓ anaphase promoting complex) pUL21A
UL22A (UL21.5)	LL (virion-associated secreted gp, modulation)	Binds RANTES (↓ CC chemokine response)
UL23* ^e	LL <i>US22</i> (tegument, modulation)	Disrupts Nmi recruitment of STAT1 (↓ IFN _γ response) pUL23
UL24	LL <i>US24</i> (tegument)	(Interacts with capsids via pUL46 and pUL85) pUL24
UL25	LL <i>UL25</i> , (tegument, modulation)	(↑ resistance to IFN, dependent on pUL26) pp85/pUL25
UL26	LL <i>US22</i> (tegument, modulation)	↓ IκB kinase (↑ resistance to IFN; ISGylated) pUL26
UL27	E (regulation)	Inhibits histone acetyltransferase KAT5/Tip60 (↑ p21/Cip1-dependent cell cycle arrest, requires UL97) pUL27
UL29-28	E <i>US22</i> (tegument pp, regulation)	(↓ p53 and NURD complex; stimulate IE expression) ppUL29
UL30	LL <i>UL30</i> (modulation)	(↓ nuclear PML and Cajal bodies) pUL30
UL30A	LL <i>UL30</i>	
UL31	LL <i>DURP</i> (modulation)	(↓ cGAS signaling)
UL32	LL (tegument pp, maturation)	Capsid proximal (↑ nucleocapsid stabilization) pp150
UL33x1-x2	LL <i>GPCR</i> (envelope gp, modulation)	(↓ pUS28, CCR5 and CXCR4 signaling)

Table 1 Continued

UL34	LL (regulation)	AAACACCGTA/T-specific DNA interaction (↓ US3/US9 transcription; enhances viral DNA synthesis) pUL34
UL35	LL, <i>UL25</i> (tegument pp, regulation)	Binds to ppUL82/pp71 (remodels of PML; ↑ expression of IE genes; supports tegumentation) ppUL35
UL36x1-x2	IE, <i>US22</i> (tegument, modulation)	Binds caspase-8 (inhibitor of caspase-8 apoptosis) vICA
UL37x1	IE (modulation)	Binds Bax and Bak (mitochondrial inhibitor of apoptosis; resistance to T cell cytolysis) vMIA/pUL37x1
UL37x1-x3	IE (membrane gp, regulation)	Gene regulation (includes UL37x1 amino terminus) gpUL37
UL38	E (tegument, modulation)	(↓ tuberous sclerosis complex ER stress and USP24-dependent lysosomal stress) pUL38
UL40	E (membrane gp, modulation)	Leader peptide binds HLA-E (↓ NK cell killing; ↑ NKG2C+ NK cell expansion) gpUL40
UL41A	LL (envelope gp)	(also called UL41.5)
UL42	(membrane gp, modulation)	Interacts with Nedd4 family E3 ligase Itch (↓ ubiquitination; ↓ cGAS response) gpUL42
UL43	LL <i>US22</i> (tegument)	
UL44	E & TL (core) (DNA synthesis)	POL complex (processivity subunit of DNA polymerase, PPS; recruits ppUL84 and ppUL112-113) pp50/ppUL44
UL45	E (core) (tegument, modulation)	Complexes with pUL48 (↓ RIPK1-dependent NF-κB activation; enzymatically inactive large subunit ribonucleotide reductase) RR1/pUL45
UL46	LL (core) (capsid assembly)	Capsid triplex complex (structural) ppUL46
UL47	LL (core) (tegument pp, entry and maturation)	pUL48 binding protein (↑ stabilization of capsid during uncoating and assembly) LTPbp/ppUL47
UL48	LL (core) (tegument pp, entry/maturation)	Capsid vertex complex (links capsid triplexes and terminase; ↑ stabilization of capsid) LTP/ppUL48
UL48A	LL (core) (capsid assembly)	Binds to pUL85 at hexon tips (structural, smallest capsid protein, SCP) pUL48A
UL49	E (membrane protein)	(Alternatively spliced) pUL49
UL50	LL (core) (nuclear membrane, maturation)	Nuclear egress complex (controls nucleus to cytoplasm transport of nucleocapsid; suppresses ISGylation) pUL50
UL51	LL (core) (maturation)	Terminase complex (DNA cleavage/packaging into capsids) ppUL51
UL52	LL (core) (maturation)	(Supports terminase function during packaging) pUL52
UL53	LL (core) (nuclear membrane, maturation)	Nuclear egress complex (controls nucleus to cytoplasm transport of nucleocapsid) pUL53
UL54	E (core) (DNA synthesis)	POL complex (catalytic subunit of DNA polymerase) POL/pUL54
UL55	LL (core) (envelope gp, entry)	Membrane fusion (heparan-binding; entry into cells) gB
UL56	LL (core) (maturation)	Terminase complex (binds <i>pac1</i> sequence to direct DNA cleavage/packaging into capsids) ppUL56
UL57	E (core) (DNA synthesis)	Single-stranded DNA-binding protein SSB/ppUL57
oriLyt	(DNA synthesis)	Lytic DNA replication origin (vRNA-1 and vRNA-2 bound)
lncRNA4.9	E (abundant, noncoding RNA)	Potential source of vRNA-1 & vRNA-2 associated with oriLyt; role in latency
UL69	E (core) (tegument, regulation)	Regulates RNA transcription/export (↑ nucleocytoplasmic shuttling; ↑ mRNA export and translation of unspliced mRNA; binds SPT6; SUMO ligase; cell cycle block) pUL69
UL70	E (DNA synthesis)	DNA helicase-primase complex (unwinds dsDNA) pUL70
UL71	E (core) (tegument, maturation)	Forms oligomers; controls secondary envelopment at ERGIG
UL72	E (core) <i>DURP</i> (modulation)	Enzymatically inactive deoxyuridine triphosphatase pUL72
UL73	LL (core) (envelope gp)	(Component of gM:gN complex) gN
UL74	TL (envelope gp, entry)	(Component of gH:gL:gO complex) gO
UL75	TL (core) (envelope gp, entry)	(Component of complexes that bind cellular receptors - gH:gL:gO and gH:gL:pUL128:pUL130:pUL131) gH
UL76	TL (core) (tegument, regulatory)	pUL31 interaction; nucleolar; translational impact on pUL77
UL77	LL (core) (capsid assembly)	Capsid vertex complex (links capsid triplexes and terminase; stabilizes capsid during assembly/uncoating) pUL77
UL78	E <i>GPCR</i> (membrane gp, modulation)	(↓ pUS28, CXCR4 and CCR5 by heterodimerization)

(Continued)

Table 1 Continued

UL79	LL (betagamma) (regulation)	Elongation factor supporting L gene transcription
UL80	LL (core) (capsid assembly)	Maturation protease (PR; N terminus) and capsid assembly scaffold protein (AP; C terminus) precursor pUL80
UL80.5	LL (core) (capsid assembly)	Scaffold protein precursor (capsid assembly) pAP/pUL80.5
UL82	LL <i>DURP</i> (tegument pp, regulation)	Major virion transactivator (localizes to and disrupts PML; degrades Daxx) pp71/ppUL82/upper matrix protein
UL83	LL <i>DURP</i> (tegument, modulation)	Scaffold for optimal tegumentation (↓ IRF3 activation) pp65/ppUL83/lower matrix protein
UL84	E <i>DURP</i> (DNA synthesis, regulation)	Binds IE2, ppUL112-113, ppUL44 and RNA/DNA hybrid (initiation of DNA replication) ppUL84
UL85	LL (core) (capsid assembly)	Forms capsid triplexes (minor capsid protein; pUL85)
UL86	LL (core) (major capsid protein)	Forms capsid (hexons and pentons) MCP/pUL86
UL87	LL (betagamma) (regulation)	TATA-binding protein (supports L gene transcription) pUL87
UL88	LL (core) (tegument, maturation)	(cytoplasmic egress) pUL88
UL89x1-x2	LL (core) (maturation)	Terminase complex (DNA cleavage/packaging into capsids; likely cleaves after <i>pac2</i> site) pUL89

^a Commonly annotated ("canonical") ORFs of HCMV. Certain genes ([#]) spontaneously mutate during isolation in human fibroblasts. HCMV mutants made experimentally may grow better than wild type (*), be indistinguishable from wild type (normal type) or exhibit one of two growth deficient phenotypes: failure to replicate (bold black[†]) or reduced replication (bold grey^{*}) when on human fibroblasts.

^b Betaherpesvirus-common genes include 40 herpesvirus core functions shown in shaded fields (labeled "core"). Gene characteristics and functional information are provided (a blank indicates the absence of information).

^c Kinetic information is based on detection of the gene product, either a protein or long noncoding (lnc)RNA.

Abbreviations: phosphoprotein, pp; glycoprotein, gp; g-protein-coupled receptor, GPCR; seven transmembrane-spanning, 7TM; immediate early, IE; early, E; leaky late, LL; true late, TL.

^d Functional information may be speculative and based on homologs in other herpesviruses if no direct evidence has been presented for HCMV.

^e Shaded fields identify the betaherpesvirus-common genes where homologs are found in the human roseolaviruses.

fibroblasts support HCMV replication, but cells from other species do not. Except for certain glioblastoma cell lines, undifferentiated or transformed cells are not susceptible to HCMV. Nonpermissive human cell lines as well as many nonhuman cells support viral entry but do not support replication owing to the presence of host restriction factors. Clinical isolates of HCMV show considerable sequence variability and sometimes represent mixtures of strains arising as a result of multiple infection or reinfection. Clinical strains undergo adaptation to cultured fibroblasts by losing expression of specific viral genes, mediated through point mutation, deletion and inversion, thereby confounding designation as well as experimental evaluation of wild type virus (Table 1).

HCMV naturally initiates infection in mucosal epithelium, disseminates within myelomonocytic leukocytes that carry the virus in the bloodstream to other locations, such as endothelial and epithelial sites, in the host. In immunocompetent individuals, virus characteristically disseminates to and replicates in ductal epithelial cells of the salivary glands and kidney tubules, allowing shedding in saliva and urine that may continue for months to years, particularly in young children. Host innate and adaptive immune mechanisms dictate the level of systemic dissemination, with a much broader tissue distribution and greater levels in infected immunocompromised individuals or newborns compared to adults with fully mature immune systems. Levels of virus infection and extent of tissue involvement dictated by host immune status determine the risk for disease following infection. Tissue samples from immunocompromised individuals with acute HCMV disease affirm that HCMV replicates naturally in epithelial, fibroblast, endothelial, macrophage, neuronal and dendritic cells. Viral antigens are readily detected in infected tissues as well as in peripheral blood neutrophils of immunocompromised individuals with a risk of HCMV disease using monoclonal antibody reagents. One of the most important, yet poorly understood aspects of host cell range, is intrauterine infection and transplacental transmission where virus gains access to the developing fetus and results in congenital disease. HCMV infection during pregnancy starts with systemic dissemination to the maternal side of the placenta and continues with access to the maternal-fetal interface but little is known about the cells involved in this medically significant process. When transmission occurs during primary infection of a pregnant woman, there is a ~40% chance that the fetus will become infected with about 10% of infected newborns showing signs of neurodevelopmental damage and disease at birth. In the case of transmission during recurrent infection, the chance of infecting the fetus has been estimated to be <1% with a similar proportion (10% of infected newborns) showing neurodevelopmental damage at birth. HCMV reactivates and is shed from ductal epithelium in mother's milk, an important route of virus transmission in the human population worldwide.

Entry into cells depends on specific envelope glycoproteins that recognize distinct cell surface receptors and lead to the fusion with plasma membrane and deposition of the HCMV nucleocapsid into the cytoplasm of the cell (Fig. 3). The cellular receptors mediating HCMV entry vary with cell type but include human platelet-derived growth factor receptor (PDGFR), epithelial growth factor receptor (EGFR), neuropilin-2, OR1411 and various integrins. PDGFR binds to trimeric envelope (gH:gL:gO) complex, mediating efficient attachment to and entry into fibroblasts and some other cell types; whereas, neuropilin-2 and OR1411 are cell surface receptors for a pentameric complex (gH:gL:pUL128:pUL130:pUL131A), that mediate attachment to and entry into

Attachment & Penetration

gB (UL55)

Fig. 3 Summary of the HCMV replication pathway with focus on herpesvirus core (red) and betaherpesvirus-conserved (black) gene products playing known or predicted roles in the viral replication cycle from entry (upper left) to release of progeny virions and dense bodies (upper right). Major steps in the productive replication cycle are indicated in large red outlined font and major activities are indicated in large gray outlined font, with black arrows indicating the procession and individual functions identified by abbreviated names. The entry pathway shown employs direct fusion at the plasma membrane (attachment and penetration) although an endocytic pathway is important in some cell types. Entry requires gB, along with gH:gL:gO and/or gH:gL:pUL129:pUL130:pUL131A, depending on the cell type. Virion tegument proteins (pUL69, pUL82, pUL35 and pUL26) are involved in regulation of the initial steps in replication. Nucleocapsid-associated pUL48, pUL47 and pUL48A are likely to control transport on microtubules, docking at nuclear pores and release of virion DNA from the capsid into the nucleus. Host cell RNA pol II is responsible for transcription of viral and host cell genes. Gene expression is regulated by products of IE genes (IE1-p72, IE2-p86) working together with E genes (UL34, UL112-UL113 and UL69) and LL genes (UL21A, UL29, UL117), together with a late gene transcription complex that includes UL79, UL87, UL91, UL92 and UL95 gene products, all modifying the activity of RNA pol II. Viral DNA replication, which also takes place in the nucleus, depends on core proteins (POL: PPS, HP and SSB) as well as three betaherpesvirus-specific gene products (UL84, UL34 and UL112–113). Capsid assembly incorporates proteins (MCP, triplex and SCP) around an AP scaffold initiated by the portal protein, as occurs in other herpesviruses. Pre-formed capsids translocate to sites of DNA replication where maturational protease Pr-AP works in conjunction with a terminase complex (UL51, UL56 and UL89) and capsid vertex complex (UL48, UL77 and UL93), together with UL97 and UL52 gene products to cleave and package viral DNA. Nuclear egress and primary envelopment at the inner nuclear membrane is under the control of UL50 and UL53 gene products and capsid stability is provided by UL32, UL48, UL47 and UL96 gene products together with UL97 protein kinase. De-envelopment at the outer nuclear membrane, translocation on microtubules to the viral assembly compartment in the cytoplasm is followed by secondary (final) envelopment controlled UL99, UL94 and UL71 gene products with the UL97 protein kinase at specific cytoplasmic membranes. Virion envelope glycoproteins follow an independent vesicle transport pathway from the ER via the Golgi body to site of final envelopment (ER-Golgi intermediate compartment) in the cytoplasm (dashed gray arrows). HCMV modifies the cellular exocytic transport pathway from sites of secondary envelopment to release via the action of the UL88 and UL103 gene products.

epithelial, endothelial and certain myelomonocytic cell types. Envelope gB is responsible for fusing the viral envelope with cellular membranes and delivering the nucleocapsid to the cytoplasm during entry regardless of cell type (Fig. 3).

Although crucial to cell tropism within the host, functions that control attachment and entry do not dictate the restricted host range characteristic of CMVs. For HCMV, this is primarily a consequence of a block to early post-entry step such that nonpermissive cells from distant host species (for example rodent) allow all steps through initial (IE) HCMV gene expression but do not support viral DNA synthesis or later phases necessary for production of progeny virus. Current evidence implicates early activation of cell death together with other host factors acting prior to viral DNA replication in restricting CMV replication within non-natural host species.

Replication Steps

The following categorical steps in replication are common across herpesviruses (depicted in [Fig. 3](#)): (1) virion binding to cell surface receptors through gH:gL complexes; (2) fusion mediated by virion envelope gB targeting the plasma membrane, either directly or after endocytosis into vesicles, and resulting in the release of nucleocapsids into the cytoplasm; (3) nucleocapsid association with microtubules with translocation to nuclear pores; (4) deposition of the viral genome out of the capsid into the nucleus; and, (5) coordinately regulated RNA pol II transcription that produces immediate early (IE), early (E) and late (L) gene products ([Table 1](#)). As with all herpesviruses, different temporal classes of genes are interspersed across the HCMV genome. For example, the 11 IE genes map to diverse locations in the U_L, U_S and IR_S/TR_S regions of the viral genome ([Table 1](#) and [Fig. 2](#)). Replication proceeds over several days before progeny virus are detected within cells or released extracellularly. Host RNA pol II transcription machinery becomes modified by virus-encoded proteins within the cell nucleus and synthesizes messenger (m)RNA as well as three types of noncoding RNAs, long noncoding RNAs, micro RNAs and ori_{Lyt}-associated vRNAs. Translation of virus-encoded mRNAs into proteins is carried out by host cell polyribosomes in the cytoplasm where active translation of several hundred uncharacterized proteins that expand the coding potential of this virus well beyond annotated genes ([Fig. 2](#)). Initially, the HCMV MIEP-enhancer provides regulatory control over the decision whether to replicate, and epigenetic regulation dictates outcome in a cell type- and differentiation state-dependent manner that is influenced by viral gene products as well as the host cell immune environment. The MIEP generally confers very strong constitutive transcriptional activity, even in nonpermissive cells, enabling this transcriptional element to be widely adapted for experimental and commercial production of recombinant proteins. Epigenetic restriction of viral transcription is interrupted by several viral modulatory proteins, both from the input tegument as well as gene products produced during infection. These balance replication, persistence, latency and reactivation in a cell-type-dependent fashion.

Tegument proteins regulate viral gene expression and modulate the host response from earliest post-entry steps through late stages of replication. Input virion tegument proteins control the release of virion DNA into the nucleus, suppress intrinsic host defense mechanisms that would otherwise restrict viral replication and mediate activation of IE gene transcription. Later, tegument proteins modulate the cell-autonomous host response and support key steps in envelopment and egress from the nucleus and cytoplasm. During the initial steps of infection, the MIEP-enhancer is transactivated by virion tegument protein complex, enhancing RNA pol II transcription of IE genes. The IE gene products activate E and L gene transcription, including E and L products from the MIE regions itself, while suppressing the host cell response to infection, innate immune cell death and cytokine-mediated immunity.

Expression of ~52 E genes requires functional IE1 and IE2 proteins. The replication cycle of HCMV is much slower than herpes simplex virus, requiring 24–36 hrs for the progression from E to L phase, 48–72 h until progeny start to accumulate, and maximum levels of virus release continuing from 96 hrs to a week post infection. Viral DNA synthesis initiates through events that depend upon a subset of regulatory IE, and E proteins ([Table 1](#)). Following initiation, the viral DNA polymerase complex assembles at replication forks together with single stranded DNA binding protein and helicase-primase complex that together produce long double-stranded DNA concatemers that are both a template for late transcription and a substrate for genome cleavage/packaging machinery ([Fig. 3](#)). All steps in replication depend on protein phosphorylation by a viral protein kinase together with host cell cycle kinases. At least two categories of L genes are encoded based on patterns of expression and dependence on viral DNA synthesis, known as leaky late (LL) and true late (TL). A late transcription complex that is also employed by gammaherpesviruses modifies the behavior of host RNA pol II to facilitate transcription of TL viral genes, likely in close collaboration with viral DNA replication machinery.

HCMV capsid formation and maturation (capsid assembly, maturation and egress from the nucleus) are largely carried out by herpesvirus core genes ([Table 1](#)). Non-core gene products provide a means to evade and engage the host response to infection for the benefit of the virus. Viral DNA synthesis and capsid assembly proceed independently in the nucleus but converge at the point where concatemeric DNA is cleaved and packaged, or encapsidated, into preformed capsids ([Fig. 3](#)), filling each progeny capsid with a unit-length genome. Seven herpesvirus core encapsidation proteins process a concatemeric DNA template by recognizing sequence-specific cleavage/packaging (*pac*) sites located near genomic termini once a genome-length molecule has been inserted into a capsid. The resulting filled nucleocapsids become stabilized by the addition of capsid-proximal tegument proteins, and then proceed through the inner nuclear membrane under control of a nuclear egress complex. Transfer of the nucleocapsid into the cytoplasm most likely occurs by initial addition of a lipid bilayer envelope at the inner nuclear membrane and removal of this envelope through fusion with the outer nuclear membrane. The tegumented capsid gains a final (second) lipid bilayer envelope at ER-Golgi intermediate compartment (ERGIC) membranes decorated by virus-encoded glycoproteins within modified region of the cytoplasm called the viral assembly compartment (VAC), an area where viral egress also occurs ([Fig. 1](#)). Dense bodies form when tegument becomes enveloped in the cytoplasm and proceeds through cytoplasmic maturation steps along with virions. Thus, mature virions, noninfectious capsid-containing and capsidless dense body particles all accumulate at sites of final envelopment within the VAC prior to release from cells. Vesicle transport (exocytosis) machinery mediates the translocation and release of virus particles. Progeny virions are composed of ~100 different virus-encoded proteins enclosing a single viral DNA molecule. The maturation process results in an excess of noninfectious and defective particles, such that only 0.1%–1% of progeny particles are able to initiate a new infection. Once maturation starts, infected fibroblasts remain viable and continue to release virus for days. A final burst of virus release accompanies the eventual death of infected cells after about five to seven days.

Epidemiology

Patterns of Infection

HCMV is a ubiquitous virus with worldwide prevalence ranging from ~60% to greater than 90%. Overall 95% of the world population becomes infected before old age. Contact with infected bodily secretions drives transmission without involvement of any intermediate host or any seasonal prevalence. Infection is typically subclinical in immunocompetent individuals. Transmission is more efficient in higher density living conditions, with larger family size and in settings of reduced hygiene. Transmission is reduced by simple measures such as avoiding salivary transfer hand washing. On a population level, HCMV is only rarely acquired congenitally (~1%). Breast milk and contact with other bodily secretions account for the majority of transmissions throughout life. Thus, infection posing a significant risk of disease when acquired in utero and is a certain risk when primary infection occurs during pregnancy. Developing areas (Eastern Europe, Africa, Asia and South America) exhibit higher rates of transmission at younger ages, than more developed areas (North America, Australia and Western Europe). Infants and young children infected with HCMV shed persistently in saliva and urine and represent important sources of new infections. In such settings, avoidance of direct contact with infected secretions and good hygiene practices reduces transmission from children to adults as well as between adults. During lifelong latency, virus may reactivate and be shed sporadically in saliva, urine and genital secretions. Blood and tissues from infected, HCMV seropositive individuals transmit virus to recipients of blood transfusions and transplants. Use of prescreened blood products from HCMV seronegative donors and leukodepletion of blood from seropositive donors has prevented transfusion-associated infections in many areas of the world.

In US-specific surveys, overall HCMV seroprevalence has remained constant at ~60% for decades, similar to other developed areas of the world. HCMV is acquired by 40%–50% of the US population by midlife, increasing to 90% by old age. Transmission patterns are influenced by host innate and adaptive immunity. Immunoprophylaxis and, particularly, vaccination would be expected to interrupt person-to-person transmission of this virus. Thus, transplacental transmission occurs much more frequently in pregnant women with primary infection than in HCMV-seropositive women with long-term infection and pre-existing immunity. The importance of adaptive cellular immunity against HCMV in preventing active infection is supported by the clinical experience in immunocompromised transplant recipients as well as AIDS. In solid organ transplantation, the HCMV seronegative recipient of an organ from a donor with long-term infection is most at risk of infection and disease. In this setting, the organ introduces the virus into a recipient. In allogeneic hematopoietic stem cell transplantation (HSCT), performed with either mobilized blood or bone marrow, the HCMV seropositive recipient of hematopoietic stem cells from a HCMV naïve host runs the greatest risk of HCMV disease. In this setting, the transplanted HCMV-naïve immune system cannot suppress virus. The nature of immune control in settings of congenital disease remains poorly understood. Whereas exogenously acquired primary infection is the sole source of virus in a HCMV-naïve woman, reactivation of latent virus, mixed infection with additional strains of virus have been observed in long-term seropositive women. All of these sources may contribute to intrauterine transplacental transmission, congenital infection and consequent disease in progeny of seropositive women.

Serologic assays provide an accurate indication of lifelong infection with HCMV, but do not provide insights into viral shedding levels or susceptibility to reinfection. Levels of antiviral antibody and cellular immunity rarely correlate in seropositive individuals. Although strain differences are recognized using virus antigen-specific monoclonal antibodies that have facilitated characterization of mixed infections, distinct HCMV serotypes are not recognized. Together with various molecular genetic approaches that assess within host viral genome sequence variation, these approaches have provided evidence that different viral strains may predominate within a single individual at different times and that such mixed infections can arise from sequential reinfection.

Virus Propagation

HCMV is most readily isolated from saliva or urine, sites of virus replication in ductal epithelial cells of salivary glands and kidney. Virus may be isolated on cultured susceptible cells from the original host species. Fibroblast cultures are most commonly used for virus isolation. The ability to replicate in epithelial and endothelial cells is lost when virus is propagated in fibroblasts because components of the gH/gL pentamer complex (UL128, UL130 and UL131) accumulate mutations. Primary or secondary cultures of epithelial, endothelial, macrophage and dendritic cells sustain gH/gL pentamer function. Additional mutations that disrupt genes that are either unnecessary or deleterious to virus replication occur. Fully wild type HCMV is very difficult to maintain in a culture. Several genes must be modified by conditional mutation. Variants of common laboratory strains, typically referred to by a single name (e.g., AD169 or Towne) have arisen as these strains have been serially propagated in different laboratories around the world. This makes comparisons between laboratories somewhat challenging even when using a strain that carries a common name. Clonal virus strains maintained as bacmids in bacteria currently predominate for experimental work; however, these strategies also generate unintended mutants and variants. Thus, clonal virus stocks should be prepared for which the full genome sequence has been determined. The difficulty of working with clinical isolates, the species specificity of replication and the rapid generation of variants when HCMV DNA is transfected into cells (or is propagated in cell culture) are well-recognized experimental confounders.

HCMV is easiest to isolate from saliva or urine of infected individuals, virus may also be isolated from semen, cervical secretions, blood cells and breast milk, particularly during primary infection. Infectious virus or viral DNA is only rarely shed in HCMV seropositive adults with clinically silent long term latent/persistent infection. DNA PCR methods have been most successful for the detection of recurrent shedding, as a surrogate for virus in saliva, urine, milk, blood, tissues and other secretions. These

methods have revealed that children with congenital or perinatal infection naturally shed virus for prolonged periods lasting up to years, that HCMV-seropositive adults shed less than 5% of the time and that shedding increases following pregnancy.

Clinical Features

HCMV infection is generally inapparent. Infectious mononucleosis can be a rare consequence but is typically less severe than that caused by Epstein-Barr virus. Women of childbearing age often encounter HCMV primary infection without showing specific symptoms. Such asymptomatic infections are the major way this virus is transmitted to offspring during pregnancy. As a consequence of viral transmission during primary or recurrent infection, HCMV remains the single most important infectious cause of congenital disease in newborns, as significant as major genetic diseases such as Down syndrome and more frequent than other genetic congenital diseases. HCMV is a classic opportunist such that infection in immunocompromised hosts results in systemic HCMV disease affecting one or more organs, referred to as CMV syndrome. HCMV has been known to unveil immunodeficiency in individuals with a previously unrecognized combined or T cell-specific immune deficit, and as such is one of the most prominent AIDS-defining infections.

As a ubiquitous herpesvirus that causes systemic infection, lifelong infection with HCMV correlates with chronic disease, immune defects and frailty, particularly in the elderly. There have been postulated contributions to atherosclerotic vascular disease, autoimmune vasculitis, systemic lupus erythematosus, Sjogren's syndrome, periodontal disease, cancer, immunosenescence and risk of some specific diseases such as Crohn's disease and glioblastoma multiforme. These associations between a common virus and chronic diseases require further scrutiny.

Congenital Disease

Congenital disease represents the hallmark of HCMV pathogenesis. This disease follows transplacental transmission to the fetus during pregnancy. The highest incidence of mother-to-child transmission occurs from the first trimester through the gestational midpoint. Neurodevelopmental disease consequences such as hearing and eyesight compromise are most common. Broader neurological symptoms recognized at birth or during childhood are less common, but important. HCMV congenital disease remains a well-recognized, though medically underappreciated public health concern. HCMV is also a substantial cause of spontaneous abortion and still birth. The at-risk population is difficult to identify because infection in the pregnant woman is asymptomatic. HCMV congenital infection affects between 0.2% and 2% of pregnancies, where transmission remains negatively correlated with socioeconomic conditions. Nevertheless, congenital disease affects roughly 20% of HCMV-infected newborns regardless of socioeconomic status, with about half of babies with disease evident at birth and half developing in the newborn over the first years of life. Left untreated, disease generally worsens. Mild, but developmentally and medically significant congenital disease is often overlooked. Demographic characteristics contribute to transmission patterns, with younger (teenage) females more likely to transmit during pregnancy than women in their twenties or thirties. Severe congenital disease is relatively uncommon but involves extensive neurological symptoms such as retinitis, microcephaly, seizures and neurodevelopmental disabilities as well as damage to the reticuloendothelial system (petechial rash, hepatosplenomegaly, jaundice, extramedullary hematopoiesis) and low birth weight. This severe disease syndrome is known as CMV inclusion disease (CID). Antiviral drugs such as ganciclovir are used to treat CID. In addition, low birthweight, premature infants transfused with blood from an HCMV seropositive donor or breast fed by an actively shedding mother risk developing systemic disease (sepsis, hepatitis, pneumonitis) that is clinically distinct from CID. By the 1970s, the spectrum of congenital CMV disease was well-characterized, although medical awareness has not improved over the intervening decades primarily because of the belief that little could be done except to address the consequent disability. It is now clear that early intervention to improve sensorineural perception improves quality of life outcomes. Except for neurological disease and multiorgan CID, intervention with antiviral drugs, either in pregnancy or in newborns, has not yielded of significant benefit. Furthermore, the substantial contribution of recurrent maternal infection to transmission worldwide and the protean nature of neurodevelopmental damage has resulted in testing for HCMV infection at birth in some countries. Overall, the disease consequences of congenital CMV can be addressed through enhanced testing, increased clinical recognition and appropriate directed therapies.

It is now very clear that, in addition to infection of HCMV-naïve women during pregnancy, long-term maternal infection also makes a substantial contribution to patterns of intrauterine infection, transplacental transmission and congenital disease. Transmission in women known to already be infected with HCMV is recognized to occur worldwide, predominating even in developed countries such as the US. Natural levels of acquired antiviral immunity provide a level of protection that apparently reduces, but that is insufficient to completely prevent transplacental transmission. The recognized benefit of natural maternal HCMV-specific immune memory has been difficult to quantify, although antiviral antibodies and T cell immunity likely impede reinfection, dissemination to the maternal-fetal interface and transplacental transmission to the fetus. Transplacental transmission occurs with a frequency less than 2% in women with long-term infection. In contrast, transmission occurs in upwards of ~40% in women with primary infection during pregnancy. Thus, prior natural exposure to HCMV provides immunity that significantly reduces risk of congenital disease.

While most newborns with congenital CMV infection survive, CID may be lethal and often results in permanent damage even when the infant is treated with antiviral therapy. Given estimated transmission frequencies of ~0.2 to 2% of live births, HCMV causes congenital disease more frequently than any other pathogen. It is estimated that there are >1 million HCMV-infected infants born each year based on a total of 150 million births worldwide. HCMV-infected young children, regardless of whether

infected in utero or postnatally, shed virus in saliva and urine for extended periods. Thus, children represent a silent, but major reservoir of virus transmitted to parents as well as other children. There is still a remarkable need to understand pathogenesis and immune control of congenital disease, including the processes of transplacental transmission and dissemination within the developing fetus.

Premature infants who acquire HCMV infection during birth or post-partum (from breast milk, horizontal transmission or blood transfusion) are susceptible to systemic disease distinct from CID. Risk factors include very low birth weight, exposure to multiple units of blood and birth to a seronegative mother who has been recently infected but has not yet started producing antibodies. Transmission of HCMV from mother's milk to newborn may be prevented by brief heat treatment (Holder Pasteurization) that inactivates infectivity but preserves nutritional benefits. Transfusion-associated HCMV disease in premature newborns is controlled by the use of blood products from seronegative (or leukocyte-depleted) donors.

Immunocompromised Host

HCMV has become one of the most common and medically important opportunistic pathogens as allograft transplantation has become more common and as incidence of HIV infection has increased worldwide. HCMV is a highly significant pathogen in immunocompromised hosts receiving immunosuppressant therapy following solid organ transplantation, during the period of engraftment following allogeneic HSCT, in the course of cancer immunotherapy and anytime cellular immune function becomes compromised. HCMV is a very common complication during HIV/AIDS. Immunodeficient or immunocompromised individuals support higher levels of HCMV replication than immunocompetent hosts, predisposing to disease.

Clinical manifestations of disease in solid organ transplant patients include systemic, febrile illness (CMV syndrome, with malaise, arthralgia and rash; neutropenia, thrombocytopenia and elevated liver enzymes), as well as a direct or indirect impact on specific organs. Disease risk has been reduced but not eliminated by preemptive therapy or prophylaxis with antiviral drugs. Clinical detection of viral antigens or nucleic acids without the need for virus culture increased the opportunity for preemptive intervention to prevent acute HCMV disease in the first few weeks following transplantation. Preemptive therapy has also benefitted allogeneic HSCT where late onset disease and indirect consequences of infection have subsequently emerged. Threshold detection nucleic acids (usually PCR detection of viral DNA in plasma or leukocytes) in blood is used to predict impending disease. Solid organ transplant recipients may develop HCMV pneumonitis, gastrointestinal lesions, hepatitis, retinitis, pancreatitis, myocarditis, and, in rare circumstances, encephalitis or peripheral neuropathy, whereas HSCT recipients typically develop HCMV pneumonitis and gastrointestinal disease. Establishing an etiologic role for HCMV requires detection of virus in affected tissue or bronchoalveolar lavage or quantification of HCMV in blood or plasma. The principle indirect effects of HCMV, particularly during solid organ transplantation, include allograft rejection, vascular disease complications and increased risk of opportunistic fungal and bacterial infections. Primary infection is most likely to lead to disease when a naïve recipient receives an organ from a HCMV seropositive donor, although the particular organ, level of major histocompatibility complex (MHC) match and immunosuppression regimen strongly influence outcome.

HIV-associated destruction of CD4 T lymphocyte during AIDS removes critical antiviral immune control, resulting in retinal, gastrointestinal, pulmonary or multi-organ HCMV disease. Disease may follow primary infection, reactivation of latent virus, and reinfection with additional strains of virus. Disease pathogenesis is complicated because HCMV shedding and viremia are common in the face of impaired cellular immunity. Clinically inapparent HCMV infection may predominate even in the face of antiviral intervention and may only progress to disease as T cell-mediated immune surveillance becomes severely compromised, such as occurs in AIDS patients with declining CD4 T cell counts.

Pathogenesis

HCMV infection and systemic dissemination precedes the development of disease; however, disease severity is not necessarily proportional to levels of virus, viral antigens or viral nucleic acid appearing in blood or tissues. Levels of virus shed in bodily secretions does not correlate with disease risk, whether considering transplacental transmission, congenital infection, transplantation or AIDS. With HCMV, direct viral damage to tissues may result from viral replication or from a combination of replication together with host inflammatory and immune response mechanisms. It is reasonable to expect that the pathogenic signature of HCMV in most settings is due to a combination of both. Direct tissue damage in severely immunocompromised patients is a hallmark of disease and develops as virus levels rise. The degree of immunosuppression matters such that HCMV disease risk increases with T cell depletion in HSCT but may be moderated by adoptive transfer of HCMV-specific T cells, by backing off therapeutic immunosuppressants in solid organ transplantation, or by the control of an immunosuppressive pathogen as seen with the rescue of HCMV immunity following highly active antiretroviral therapy (HAART) in AIDS. In such settings, the levels of HCMV DNA in the bloodstream provide an accurate indication of disease risk and is the basis of monitoring for pre-emptive therapy. Antiviral CD8 T cells are the primary immune mechanism for bringing HCMV under control in transplant settings. Shortcomings in this arm of immunity underlie late onset disease.

In AIDS, antiviral CD4 T cells provide crucial support of overall immunity. HAART suppresses HIV replication in these T cells, reconstitutes or preserves cellular immune function, and thereby eliminates risk of HCMV retinitis, gastrointestinal disease and other problems associated with AIDS progression. This reconstitutes immunity and leads to a risk of uveitis where inflammatory disease is triggered by HCMV antigens in the affected tissues.

It is settings of less dramatic immune compromise, including pregnancy, where transplacental transmission results in congenital disease in offspring, that the host response to infection is suspected of making contributions to pathogenesis. Pregnancy is a state of relative maternal immune compromise, resulting from maternal tolerance of fetal antigens in a complex and changing immune environment. Transmission and intrauterine replication may be enhanced by inflammatory damage. Fetal immune response patterns, though not fully developed, may contribute to virus control as well as risk of sensorineural damage in congenital disease.

Transmission

HCMV transmission requires contact with virus-containing body fluids, as is the case with most human herpesviruses. HCMV is shed, often for prolonged periods of time, in urine, saliva, tears, semen and cervical secretions, as well as in breast milk. HCMV transmission rates are highest following direct contact with body fluids. Two distinct types of exposures are associated with horizontal transmission of HCMV: sexual transmission in adults and contact with urine or saliva from young children or saliva from adults. Infection is often transmitted among children and from young children to parents. One of the highest risk populations for acquisition of this virus is therefore an HCMV naïve pregnant woman who is a parent or caregiver of young children. This setting places the woman at risk of infection herself as well as of transmitting to the developing fetus. Adults may shed virus for weeks after primary infection as well as sporadically throughout life. General hygiene practices, such as regular hand washing, reduce transmission. Although HCMV shedding is common among hospitalized individuals, particularly immunocompromised patients, good hygiene practices by medical care professionals generally prevents HCMV transmission. Transmission via blood transfusion and HSCT has been reduced by donor screening. Transplantation of solid organs and tissues from seropositive donors to HCMV naïve recipients very efficiently transmits HCMV and remains clinically significant.

HCMV is transmitted vertically during pregnancy, during birthing as well as via breast milk, a pattern that is distinct from roseolaviruses, alphaherpesviruses or gammaherpesviruses. In developed countries such as the US, primary infection occurs in a small proportion of pregnant women where there is a high risk for transplacental transmission. Approximately 40% of newborns delivered by women with primary infection show signs of HCMV infection, compared to only 0.2% to 2% of newborns delivered by long-term HCMV-seropositive women. Transmission at birth as well as through mother's milk helps maintain HCMV infection in the population, with between 25% and 50% of infants nursed by seropositive mothers acquiring HCMV by one year of age. Importantly, disease sequelae are not generally associated with intrapartum or post-partum acquisition of HCMV in full-term newborns; however limited acute disease has been observed in rare cases.

Persistence and Latency

HCMV infection is lifelong. HCMV seropositive individuals are at risk of disease due to virus reactivation should they become immunocompromised. Tissues and organs from these individuals can transmit infection to naïve transplant recipients, a clear indication that this virus persists in cell types with a wide distribution. Based on detection of viral DNA, natural latency occurs in CD34 + stem cells and CD14 + lineage-committed granulocyte-macrophage progenitors that give rise to macrophages and dendritic cells, but not in mature granulocytes or lymphocyte populations. In HCMV seropositive individuals, very few (0.004% to 0.01%) bone marrow-derived mononuclear cells carry a few genome copies of viral DNA. Somewhat surprisingly, HCMV gene expression during lifelong quiescent infection is characterized by the same subset of early and late genes that are expressed during acute infection, albeit at lower levels in the very small proportion of bone marrow-derived hematopoietic cells that carry viral DNA. On the one hand, this diversity of viral gene expression contrasts the restricted latent gene expression of other herpesviruses. On the other hand, the question of whether HCMV persists in a chronic active infection rather than as latent virus remains for experimental consideration. It may certainly be the case that the balance of persistence and latency is determined at the level of the individual infected cell. The presence of viral DNA and gene expression are strong indications that myelomonocytic lineage cells are the reservoir of lifelong HCMV infection. Sporadic shedding that is observed in immunocompetent individuals may be due to reseeded ductal cells in the salivary gland by these myeloid cells; however, it remains possible that ongoing replication in ductal epithelium (or elsewhere) may seed the leukocytes and be responsible for the observed patterns of gene expression.

Leaving aside the complexities, quiescent infection is observed naturally in progenitor (stem) cells from the bone marrow (myeloid lineage), characterized by an absence of IE gene expression with repressive chromatin structure metering epigenetic control over virus replication. Despite ambiguities, several viral protein and RNA gene products have been implicated in latency and differentiation-dependent reactivation or in modulation of the host immune control over latency. HCMV infection of CD34 + stem cells drives differentiation towards monocyte-like cells dependent on inflammatory nitric oxide and STAT3 transcription factor under the influence of the virus-encoded US28 chemokine receptor. Thus, even in the absence of immune control, immature myeloid cells carry viral DNA without supporting replication and retain the potential to reactivate upon differentiation. The generation of macrophages or dendritic cells from infected myeloid progenitors, typically achieved by stimulation with proinflammatory cytokines, results in viral IE gene expression and replication. Clinically relevant reactivation in allogeneic transplant settings appears to depend on the elaboration of

proinflammatory cytokines that are themselves components of tissue rejection. Untreated, patients with compromised immunity to HCMV undergo a pattern of uncontrolled viral replication that results in disease. Clinical reactivation occurs in settings such as severe trauma or bacterial sepsis, where inflammation and the consequences of tissue damage suffice to induce replication possibly as a consequence of reperfusion injury. Severely immunocompromised patients, such as terminal AIDS patients, support high levels of HCMV replication with associated disease. Pregnancy in long-term seropositive women supports viral replication at levels that pose a small, but important risk of congenital infection in offspring.

Immunity

HCMV is subject to innate immune control, including via cell death, cytokines and natural killer (NK) cell mechanisms. This virus is controlled by pathogen-specific adaptive immunity mediated by T cells and, to a lesser extent, antibodies. On one hand, virus-specific cellular immunity is crucial for lifelong control over HCMV. NK and T cells collaborate to control of acute infection. Memory T cell surveillance suppresses replication and sustains clinical latency. Immunocompromised hosts with defects in cellular immunity are particularly susceptible to HCMV, as illustrated by increased disease in long-term HCMV seropositive recipients of hematopoietic cell transplants from HCMV naïve donors as compared to allogeneic transplants from MHC-matched long-term HCMV immune donors. In such settings, despite sustained serum antibody levels, host control depends on donor memory T cells that may be enhanced by administration of MHC-matched CMV-specific CD8 T cell therapy. On the other hand, anti-HCMV antibody makes a contribution to host resistance, best illustrated by the long-standing observation that transferred maternal antibody prevents transfusion-acquired HCMV in low birthweight infants. In addition, an envelope gB subunit vaccine reduces rates of infection in HCMV naïve women that is likely due to an antibody-mediated mechanism. Finally, there is growing consensus that intravenous immune globulin with HCMV-specific antibody helps reduce intrauterine infection, transplacental transmission and congenital disease.

HCMV emergence (whether amplification of persistent virus or reactivation from latency) is triggered by inflammatory signals and likely occurs sporadically throughout life even in fully immune individuals. This results in restimulation of HCMV-specific immunity such that memory T cells accumulate to exceptionally high levels with age. This cellular immunity affords protection because, once compromised, virus levels increase and disease consequences follow. The immunocompromised host provides the most convincing setting where HCMV control by T cell immune surveillance is crucial, supporting the widely held view that a cellular immune response, particularly by NK and memory T cells, maintain lifelong infection in immunocompetent individuals.

Modulation of the Host Response to Infection

HCMV commits most of its genome coding capacity to altering the host response to infection within the infected host cell and organism (**Table 1**). All classes of viral gene products (IE, E and L, as well as those associated with latency) contribute to the modulation of the host response to infection. These viral functions (whether protein or RNA) are typically not required replication in cultured cells. There are three major categories of such functions: (1) those acting within the infected cell (cell autonomous), modulating gene regulation, pathogen sensing, cellular metabolism, cell cycle and cell death pathways; (2) those acting within the host organism at the innate immune level, modulating innate cytokine and cellular responses; and, (3) those acting within the host organism at the adaptive immune level, modulating T and B cell immune effector mechanisms and memory. The virus employs modulatory functions to either evade host clearance mechanisms or to exploit host response pathways. Either way, these viral functions serve to enhance viral infection, pathogenesis and persistence. As with other herpesviruses, most of these functions are committed to suppressing host immunity. However, HCMV encodes cytokines and chemokines as well as chemokine receptors that exploit cytokine-dependent signaling within infected cells to benefit systemic dissemination. One recent insight shows that viral chemokine receptor US28 signaling drives differentiation of hematopoietic stem cells to become a dedicated monocytic reservoir of infection. Such fundamental orchestration of cellular development serves to ensure lifelong persistence.

Modulation of cell autonomous response to infection

HCMV gene products deflect intrinsic host cell antiviral responses mediated at the transcriptional level through activation of the cytokine pathways, cell stress, cell cycle, metabolism and cell death (**Table 1**). Protein-coding genes counteract host cell epigenetic downregulation of gene expression as well as interferon (IFN) activation. Similarly, epigenetic regulation involved in switching from latency to reactivation are influenced by viral regulatory proteins. Pathogen recognition receptor for DNA cGAS, NF- κ B activation and IRF3 activation are all targeted by multiple viral proteins. Inflammatory transcriptional activation, IFN response, and IFN-dependent activation of protein kinase R and 2',5' oligoadenylate synthetase are all suppressed. During productive infection as well as latency and reactivation, HCMV enhances signal transduction through TNF receptors and encodes a chemokine receptor to interface with cellular chemokines and chemokine receptors and dramatically enhance cell activation, migration and differentiation, potentially to benefit replication as well as latency and reactivation. HCMV-encoded chemokine likely recruit leukocytes to benefit the virus and host FLT3R becomes activated and enhances viral persistence in stem cell models of latency.

In a manner that has been compared frequently to tumor viruses, HCMV dramatically alters cellular metabolism and stress markers, downregulating ER and lysosomal stress, upregulating the unfolded protein/integrated stress response as well as tyrosine kinase signaling, activating certain cell cycle processes but imposing a striking block to cellular DNA synthesis. HCMV suppressed

various cell death pathways via both protein and RNA gene products engaging mitochondrial targets such as BCL2 family members Bax and Bak as well as caspase-8 to prevent apoptosis and alternate death pathways driven by serine proteases and protein kinases. These functions appear to foster an environment in infected cells that sustains infection, whether the outcome is productive replication or persistence.

Modulation of the innate immune response to infection

HCMV modulates cytokine signaling and encodes cytokine, chemokine, chemokine binding protein and chemokine receptor strategies to respond to host chemokines attract granulocytes and monocytes, apparently orchestrating the inflammatory response. This virus disarms the innate NK cell response through a large number of strategies sequestering ligands, impeding receptor engagement and mimicking MHC, all with the apparent goal of evading NK cell killing.

Modulation of adaptive immune response to infection

Natural HCMV infection is highly immunogenic, resulting in broad humoral antibody as well as cellular T lymphocyte responses that persist for life and maintain control over the virus infection. Immune responses to certain viral antigens are slow to develop, likely due to virus modulation of adaptive antibody and T cell responses. The antibody response to HCMV is targeted by several virus-encoded IgG Fc receptors, some of which also enhance virus spread dependent on the presence of antiviral antibody. T cell immune surveillance provides crucial control preventing amplification of virus throughout life. Some of the first HCMV-encoded immunomodulatory functions discovered downmodulate the ability of T cells to recognize HCMV-infected cells. Thus, MHC class I antigen presentation is reduced, while cellular and virus-encoded cytokines act together to impede T cell activation and effector function to benefit the virus. An important immunomodulatory impact of HCMV infection is that the antiviral T cell response is sustained at very high levels and increases with age of the host, a phenomenon called "memory inflation".

Diagnosis

Diagnosis of HCMV progressively improved from the 1980s and 1990s as virus isolation methods gave way to rapid immunological and, particularly, nucleic acid detection that are more rapid, less costly, quantitative and potentially automatable. HCMV DNA is readily detected in the tissues, plasma, leukocytes and whole blood of individuals at risk of developing HCMV disease. Immunohistochemical detection of HCMV antigens in biopsy samples and blood can confirm infection. Commercial diagnostic tests that rely on quantification of viral DNA in whole blood or plasma are in common clinical use. DNA amplification (predominantly PCR) methods are used to monitor at-risk populations with the intention to preemptively treat when levels of viral DNA reach a threshold value predictive of impending disease. The levels of viral DNA in the bloodstream are predominantly cell-associated but detected proportionally in plasma as well, providing an accurate prediction of disease risk. Detection of HCMV DNA in saliva, urine or dried blood spots of newborns within the first three weeks of life is diagnostic of transplacental transmission during pregnancy; however, levels of shedding in this or any other clinical setting does not predict disease severity in the infected host. Widespread HCMV screening of newborn blood spots facilitates the recognition of newborns at-risk of HCMV congenital disease who should be monitored for progressive hearing loss during early childhood.

Prophylaxis and Treatment

Antiviral prophylaxis has proven to be very effective in preventing HCMV disease in solid organ transplant recipients. However, late onset HCMV disease may follow prophylaxis in as many as 5% of patients. Prophylaxis or preemptive antiviral treatment in hematopoietic cell transplant recipients reduces the incidence of HCMV disease during the first 3–4 months from >80% to around 5%, significantly reducing mortality in adults and, particularly, in children. Late onset disease, usually more than 100 days after transplant, remains a clinical challenge. Long-term HIV antiviral therapy reduces incidence of HCMV disease in AIDS patients, although HCMV remains a significant risk in HIV-positive individuals when CD4 T cell counts drop to low levels, triggering HCMV-specific therapeutic intervention.

The advent of antiviral drugs such as ganciclovir (and valganciclovir), cidofovir, foscarnet, and letermovir, has allowed better clinical management of HCMV disease. Despite therapeutic intervention, this virus remains medically significant. The incidence of HCMV pneumonia in allogeneic HSCT as well as the preponderance of HCMV retinitis AIDS contributed to the development of antiviral drugs ganciclovir, foscarnet and cidofovir as well as to the development of orally administered valganciclovir for therapy. Most recently, letermovir for has been approved for antiviral prophylaxis. Valganciclovir, ganciclovir, foscarnet and cidofovir are approved for treatment of HCMV disease in the USA. All of these target the viral DNA polymerase to block viral DNA replication, with ganciclovir, valganciclovir and cidofovir acting as nucleoside analogs, and foscarnet acting as a pyrophosphate analog. Intravenous ganciclovir and orally administered prodrug valganciclovir are first choices in most settings for prophylaxis, preemptive therapy or therapy of active disease. These antiviral drugs come with significant toxicities. The antiviral, letermovir targets viral genome packaging machinery and is orally administered like valganciclovir but lacks toxicity so enables earlier prophylaxis in allogeneic HSCT. Additional oral drugs such as maribavir, targeting the UL97 protein kinase, have been under development. Prolonged use of any investigational or licensed drug

selects for resistant virus. Importantly, drug resistant mutants may complicate clinical management of the patient; however, fitness compromise of drug resistant mutants is such that they have not been found to circulate in the community.

Prevention

The medical significance and impact of HCMV congenital disease is recognized worldwide, making the development of a vaccine a universal public health priority. Attempts to develop live, attenuated, killed and subunit vaccines over the past 50 years have not yet resulted in a licensed product. The Centers for Disease Control and Prevention currently recommends that parents and caregivers of young children be informed of how HCMV is transmitted and of hygienic measures that reduce transmission, particularly to women who care for young children and may become pregnant.

The significantly lower rate of congenital disease following recurrent compared to primary maternal infection during pregnancy supports the potential benefits of universal vaccination. The limited success of a gB subunit vaccine strategy in reducing new infections by half in women of childbearing age lends a note of optimism that effective prevention may be possible. Additional subunit, mRNA and vectored vaccines incorporating gB along with the gH:gL pentamer plus antigens to stimulate T cell immunity are being evaluated as candidates for universal vaccination to prevent congenital infection or to protect stem cell and solid organ transplant recipients. Replication defective HCMV vaccines are also under clinical evaluation. Some vaccines are focused on recipients of organ and tissue transplants. Vaccines must either reduce transmission or suppress viral replication in tissues and organs depending on the clinical setting.

Future Perspectives

Despite tremendous gains in knowledge of HCMV molecular biology and pathogenesis, this virus continues to be a medically challenging cause of disease especially for immunocompromised hosts and early in fetal development. To date, antiviral chemotherapy has been only partially successful in controlling HCMV infection in transplant and other immunocompromised patients. There remains a continued and pressing need for vaccination to reduce the incidence of congenital HCMV infection. An important goal for future research will be to translate the large and growing body of basic knowledge of HCMV biology into improved treatments and effective vaccines.

Glossary

Combinatorial antiretroviral therapy (cART) Combination antiretroviral therapy is the current standard of care for those living with HIV-1. These regimens are often described as a “cocktail” of different antiretrovirals that keep the virus from replicating via varying modes of drug action. First line cART usually consists of two nucleoside reverse transcriptase inhibitors and an integrase inhibitor.

Latent Reservoir Refers to the HIV-1 DNA that remains integrated in host cells following suppression of viral replication using cART. These viral genomes are generally not actively being expressed to produce infectious virus but do so stochastically and thus are responsible for viral rebound when antiretroviral therapy is stopped. Much of the latent reservoir is composed of defective viral genomes with intact genomes making up only a fraction of the viral sequences that persist as DNA in cells.

Reverse transcription The process of using single-stranded viral RNA as a template to produce full-length, double-stranded viral DNA.

RNA splicing A form of RNA processing that allows the generation of multiple messenger RNAs from a single large precursor RNA leading to the translation of multiple different proteins. This process is often utilized by viruses that have smaller genomes to increase protein diversity.

Virion A term used to describe a fully budded viral particle.

90–90–90 Initiative An initiative from the World Health Organization that aims to have 90% of all infected individuals aware of their infection status, 90% of those aware of their status in care and taking ART, and 90% of those taking ART to have the drugs fully suppressing viral replication.

Classification

The human immunodeficiency virus type 1 (HIV-1) is an enveloped, plus-stranded RNA virus of the *Retroviridae* family, further classified into the orthoretrovirus subfamily. The name retrovirus implies a special feature of the viral life cycle - the reverse flow of genetic information. Retroviruses reverse the usual flow of genetic information where DNA is used as a template to synthesize RNA (transcription) to now include a step of *reverse* transcription where viral RNA is used as a template to synthesize viral DNA. Many of the drugs used to control an HIV-1 infection target the viral DNA polymerase (called Reverse Transcriptase or RT) to block the step of reverse transcription.

There are a number of genera in the *Retroviridae* family, and HIV-1 is part of the *Lentivirus* genus. Lentiviruses have a worldwide distribution and have been found in cats, sheep, goats, horses, cows, and rabbits. Within the *Lentivirus* genus is also a lineage of primate lentiviruses, with HIV-1 being a member of this lineage.

The Origin of HIV-1

There is an important milestone that puts a time boundary as to when lentiviruses entered the primate lineage. Specifically, about one-half of the approximately 70 primate species in Africa are infected with a primate lentivirus (collectively called simian immunodeficiency viruses, or SIV) while none of the primates in the Americas are naturally infected. Thus we can infer that a lentivirus entered the primate population in Africa after the split of old world and new world primates and has spread through that population. In these naturally occurring infections the virus is rarely pathogenic, in contrast to the infection of humans with HIV-1.

Sequence analysis of viral genomes has become a powerful tool for tracking the history of viruses, and this tool has been especially important for understanding the HIV-1 epidemic. The SIV most similar to HIV-1 is found in chimpanzees ([Fig. 1](#)). Using sequence analysis of the viral genome we can infer that two different SIV lineages (from two other primates: SIVrcm from red-capped mangabeys and SIVgsn from greater spot-nosed monkeys) infected a chimpanzee and recombined to create a virus that could grow and adapt in chimps (SIVcpz). Given the similarity between chimps and humans this meant that to a large extent this adaptation would also improve replication in humans. About 100 years ago a single transmission event between chimps and humans occurred that gave rise to what we know as the HIV-1 epidemic, a lineage of virus in humans known as the main or M group. Chimpanzees have been used as food sources for human populations, with hunting and dressing carcasses being an obvious path for the introduction of these viruses into humans. It is hypothesized that this is how the first transmission event of SIV from chimpanzees to humans might have occurred. In addition, several other closely related SIVcpz strains have been transmitted to humans (possibly with gorillas as an intermediate) but these have not reached epidemic proportions as the M group lineage has.

Fig. 1 Phylogenetic tree of the SIV and HIV lineages. Phylogenetic analysis of SIV and HIV sequences shows that each HIV-1 group (M, N, and O) originated from an independent transmission event of chimpanzee SIVcpz to humans followed by diversification into subtypes (e.g., Group M into Subtypes A, B, C, etc.). This analysis also demonstrate how HIV-2 has been transmitted multiple times to humans from its origin as SIVmm in sooty mangabeys. Figure adapted from Kuiken, C.L., Foley, B., Hahn, B.H., *et al.*, 1999. Human Retroviruses and AIDS: A Compilation and Analysis of Nucleic Acid and Amino Acid Sequences. Theoretical Biology and Biophysics Group. Los Alamos, NM: Los Alamos National Laboratory.

There is a second SIV that has infected humans, known as HIV-2. This virus is most similar to an SIV found in sooty mangabeys (SIVsm). The SIV of sooty mangabeys has been transmitted into humans a number of times giving rise to the smaller epidemic of HIV-2 in west central Africa with a virus that is significantly less pathogenic than HIV-1.

Organization of the Genome

HIV-1 has a single-stranded RNA genome of about 9700 nucleotides that is packaged into the virion as two identical copies of RNA (**Fig. 2(A and B)**). The genomic RNA is plus stranded, meaning it is in the same polarity as its messenger RNAs (i.e., the strand that can be translated into protein). However, for retroviruses the genomic RNA is not translated when it enters the cell but rather copied into double-stranded DNA. Thus the genome exists in two states, genomic RNA that is packaged into the virion and a DNA copy of the genome that is integrated into the host cell genomic DNA. Once integrated into the host genome, transcription of viral DNA into RNA begins. Only one transcript type is made – a full length transcript equivalent to genomic RNA (**Fig. 2(C)**). The transcript is made by the cellular RNA Pol II and processed by cellular machinery, so it looks like a cellular mRNA with a 5' cap and a 3' poly A tail (**Fig. 2(A)**). The RNA and DNA forms of the genome are very similar, retaining the gene order. However, during DNA synthesis portions of the RNA sequence at the ends of the RNA are rearranged and duplicated at the ends of the DNA to give the DNA long terminal repeats (LTR; **Fig. 2(C)**). These duplications are mediated during DNA synthesis by a short direct repeat at the ends of genomic RNA called R. This allows the virus to place in its DNA form the transcription regulatory signals in U3 upstream of the transcription start site, signals that are duplicated near the 3' end of the RNA and thus not lost when they are excluded from the transcribed RNA at the 5' end. In the 5' untranslated region (UTR) the genome folds into extensive secondary structures with important regulatory functions. This region contains a packaging signal, ψ (Psi), that identifies the viral genome as the RNA that should be packaged into newly forming viral particles. Genomic RNA is packaged in dimers and a dimerization signal (DIS) initiates the dimeric folded structure.

Downstream of the 5' UTR are the viral genes. HIV-1 has 10 genes (*gag*, *pro*, *pol*, *vif*, *vpr*, *tat*, *rev*, *env*, and *nef*). Like the 5' end of the genome, the 3' end of the genome also contains sequences that function in the RNA that are important for replication (such as the polyadenylation signal).

Fig. 2 HIV-1 virion structure and genome. (A) The HIV-1 RNA genome is approximately 9.7 kilobases and consists of 10 genes (shown with boxes) that code for 15 mature proteins. Each end of the RNA genome is comprised of a repeated sequence known as R with sequences inside of R labeled as U5 near the 5' end and U3 near the 3' end. The 5' and 3' untranslated regions (UTR) encode cis-acting replication signals as described in the text. Genomic RNA has the hallmarks of a eukaryotic RNA with a 5' cap and a 3' poly A tail. Also shown is the major splice donor site D1 and the other splice donors D2-D4, as well as the positions of the major splice acceptor sites A1-A5 and A7. (B) The HIV-1 particle is spherical, approximately 100 nm in diameter, and has a modest number of Env protein trimers (maroon) in its membrane envelope that facilitate entry into the host cell. The particle contains several structural proteins that dictate its geometry, including the matrix (MA; blue) and capsid (CA; green) proteins. Additionally, the particle is prepackaged with functional proteins reverse transcriptase (RT; orange) and integrase (IN; pink), and also includes the viral protease (PR; blue) which functioned during assembly/maturation. Two identical plus strands of viral RNA comprise the viral genome, which is contained in the capsid cone of the virion. (C) Through reverse transcription, HIV-1 RNA (red) is copied into double-stranded linear DNA (blue) that is then integrated into the host cell genome. DNA synthesis creates a direct repeat of sequences that in the RNA were discontinuous (U3 R U5, blue box), with this direct repeat called the long terminal repeat, or LTR. Following integration, the viral promoter within the LTR (U3) drives expression of the DNA form of the genome into full length RNA, creating new viral RNA to be packaged into assembling virions or used in the expression of viral proteins (with or without RNA splicing).

Expression of Viral Genes

The full-length 9700 nucleotide-long transcript can be used either as genomic RNA and packaged into virions or as a messenger RNA. In eukaryotes only the 5' most reading frame can be translated on an mRNA. For HIV-1 this means that when the full-length transcript serves as an mRNA it is for the *gag* gene. About 95% of the time, a Gag protein is synthesized and translation stops at the end of the *gag* reading frame. However, embedded in the RNA near the end of the *gag* coding region is a stretch of uridines and a stem-loop structure that occasionally (5% of the time) causes the ribosome to slip back one nucleotide while decoding the RNA (−1 frameshift); this changes the reading frame the ribosome is in with translation now continuing into the *pro* and *pol* genes creating a Gag-Pro-Pol polyprotein precursor. This is one strategy the virus uses to get around the limitation of having translation limited only to the 5' most open reading frame of an RNA.

The other strategy the virus uses to express its downstream genes is RNA splicing. Splicing is used in the expression of most cellular genes to excise introns from a long RNA precursor and piece together the exons that make up the final mRNA. This is what happens to the virus except here the internal regions of the genome serve as either exon or intron, depending on which gene is being expressed. The cellular splicing machinery generates over 40 spliced mRNAs from the full length genomic viral RNA, and a simplified scheme of these splicing events is shown in Fig. 2(A). If the full-length transcript is spliced, it always uses the main splice donor D1 (in the 5' UTR) and splices to one of the downstream acceptors, A1-A7. Splicing excises the section of the genome under the arc, so, for example, a splice to A1 removes the section between D1 and A1 (Fig. 2(A)). This joins the 5' UTR to the translation start site for the *vif* open reading frame (which is just downstream of the A1 splice site) to make a transcript that will be translated to generate Vif protein. Similarly, splicing to the other acceptors moves the translation start sites for each of the downstream genes next to the 5' UTR to allow it to be translated. There are still several twists. First, both the *env* and *vpu* open reading frames are

translated from the same mRNA (bending the rule of only the 5' most reading frame being translated). Second, RNAs that are spliced at D1 may or may not splice again from D4 to A7. The exons for Tat and Rev span this D4-A7 splice site, requiring the D4-A7 splice to form their complete open reading frames but at the expense of the intact *env* reading frame.

The D4-A7 splicing event is regulated to allow the formation of mRNAs for Tat, Rev, and Nef when splicing occurs, and both the full length genomic RNA and mRNA for the Env protein when splicing is blocked. Cells typically require RNAs to be fully spliced in order to leave the nucleus, and the mRNAs for Tat, Rev, and Nef follow this rule (and the normal cellular mRNA export pathway). However, for the unspliced genomic RNA and partially spliced *env* mRNA (retaining the D4-A7 intron) the virus must trick the cell to export these RNAs. The viral Rev protein binds to a region of RNA secondary structure in the *env* intron called the Rev Response Element (RRE) and links the unspliced and partially spliced RNAs to an alternative RNA export pathway by binding to the host protein CRM1 to move these RNAs out of the nucleus and into the cytoplasm.

Virion Proteins

Most of the viral proteins that are found in the virion are initially synthesized as larger polyprotein precursors that must be cleaved by a protease. Thus the *gag* gene encodes the Gag polyprotein precursor that is targeted to the cell plasma membrane where the virus buds out of the cell. During virion formation/maturation the viral protease (see just below) cleaves the Gag protein into its membrane-bound, N-terminal matrix (MA) protein, its capsid (CA) protein that will form the characteristic cone structure within the enveloped virus, its nucleocapsid (NC) protein which binds the viral RNA, and the C-terminal p6 protein which is involved in interacting with a host cell pathway to allow the membrane that surrounds the budding virus to pinch off and leave the cell.

Approximately 5% of the time translation of Gag slips into the -1 reading frame to create the Gag-Pro-Pol polyprotein precursor. When the Pro domain dimerizes this creates the viral protease (PR), which is responsible for cleaving the Gag and Gag-Pro-Pol polyprotein precursors. This happens during the budding/maturation process. The protease is responsible for cleaving itself out of the precursor, for cleaving Gag, and for releasing the viral DNA polymerase reverse transcriptase (RT). The protease cleavage event at the C terminus of RT releases the viral integrase protein (IN). PR and RT function as dimers, while IN functions as an even higher order oligomer. The p6 domain at the C terminus of Gag has a binding site for the viral Vpr protein. There are about 2000 copies of Gag in a virion, 100 copies of the Gag-Pro-Pol precursor, and 75 copies of Vpr.

The other major viral protein is the envelope or Env protein on the surface of the virion. It takes a different path to the assembling virion. As a membrane protein, it is synthesized in the endoplasmic reticulum (ER) in the cell with the N terminus threaded into the lumen of the ER until the appearance of an encoded translocation stop signal about 200 amino acids from the C terminus of Env. The initial protein is called gp160 based on its apparent molecular weight and the fact that it is highly glycosylated. The protein trimerizes and migrates to the cell surface, always embedded in the membrane near its C terminus. In the Golgi, a cellular protease (furin) cleaves the protein into two subunits: an extracellular surface protein gp120 (SU) and the transmembrane protein gp41 (TM), with the gp120 and gp41 subunits maintaining noncovalent interactions. The final Env trimer is composed of three subunits of gp120 and three subunits of gp41. For HIV-1 there are only about 10–20 trimers on a virion, occupying only a small amount of the surface of the enveloped virus. gp120 interacts with the CD4 protein on the surface of helper T cells to determine which cell gets infected, i.e., CD4 is the primary receptor for the virus. After binding CD4, gp120 goes through a series of conformational changes to create a binding site for a coreceptor, usually a cellular surface protein called CCR5. After binding these two cell surface proteins, gp41 then mediates fusion between the viral and host cell membrane to allow entry of the capsid into the cytoplasm of the cell, where viral DNA synthesis occurs. Small amounts of other viral and cellular proteins have been reported to be associated with virions but these are largely of unknown significance.

The Other Viral Proteins Work Intracellularly

All retroviruses encode the main replicative proteins Gag, Pro, Pol, and Env. For some retroviruses these are the only proteins encoded in the viral genome. Other retroviruses encode a variety of additional proteins, often called accessory proteins since they are in addition to the replicative proteins. However, adapter proteins might be a better name since most of them function to bring together proteins in the cell (think an adapter for an electrical plug) in ways that benefit the virus. HIV-1 encodes six such proteins: Tat, Rev, Nef, Vif, Vpr, and Vpu.

Tat and Rev play critical roles in initiating the expression of the viral genome. The newly integrated viral DNA is transcribed by RNA Pol II from the host cell. However, most of the initial transcripts are short, with only a fraction being full length, with these few full length RNAs being spliced to form Tat and Rev mRNAs. The initial Tat protein that is synthesized binds to a feature of RNA secondary structure at the 5' end of the RNA, a structure called the TAR loop. In this way the Tat protein recruits the transcription and elongation factor P-TEFb. P-TEFb includes a protein kinase (CDK9) which phosphorylates the C terminus of RNA Pol II to increase its elongation efficiency allowing the synthesis of more full-length RNA. In parallel the early Rev protein binds to the RRE to allow partially spliced and unspliced viral RNAs to exit the nucleus thus allowing for all of the viral RNAs, including the unspliced genomic RNA, to exit the nucleus (as described above).

The viral Vif, Vpr, Vpu, and Nef proteins counteract cellular antiviral restriction factors and regulate cell processes to suit viral replication. These proteins have multiple targets and effects. However, a common theme is to bind a cellular protein that has a deleterious effect on viral replication and link it to the proteasome where it gets degraded.

A clear example of how this group of viral proteins acts as an adapter is seen with Vif. Vif targets the cellular factor APOBEC3G for proteasomal degradation. In the absence of Vif, APOBEC3G is packaged into virions and causes cytosine deamination in the minus strand of viral DNA during reverse transcription in the next cell, which results in G to A mutations in the positive strand. The minus strand is initially present as single-stranded DNA and this is the target of APOBEC3G. Viruses lacking Vif are unable to grow in cells that produce APOBEC3G. Vif brings APOBEC3G to a cellular ubiquitin ligase where it is ubiquitinated, targeting it for degradation by the proteasome. Vpr also binds to a cellular ubiquitin ligase but its host cell target is still a focus of research. Vpr induces the infected cell to arrest in the G2 phase in the cell cycle, perhaps to induce DNA repair enzymes that ultimately assist in integration. However, such activity would have to be carried out by just the Vpr packaged in the virion since integration happens before viral gene expression. The extent to which the small amount of virion-associated Vpr is the effective form of the protein or if it has functions after expression of larger amounts of protein after integration is unknown. Vpu counteracts the cellular tetherin protein. Tetherin binds to both the cellular membrane and to the membrane of the newly budding virus, thus tethering the virus to the cell surface. Vpu reduces the amount of tetherin on the cell surface. Nef has multiple functions, such as down regulation of CD4 from the surface of the cell to reduce interaction with the newly synthesized Env trimers, down regulation MHC class I from the surface of the cell to reduce immune surveillance, reduction in the amount of SERINC5 which when incorporated into the virion inhibits subsequent fusion to the next cell, and interacting with a cellular kinase to affect cellular activation.

Life Cycle

It is convenient to divide the viral life cycle into two phases: an early phase starting with binding of the virus particle to the target cell through the integration of viral DNA, and a late phase starting with transcription of the integrated DNA through virion budding and maturation.

Early Phase

Attachment and Entry

The first step of the virus life cycle is attachment to the host cell via the CD4 protein on the surface of helper T cells using the gp120/SU portion of the Env protein (**Fig. 3**). The normal form of HIV-1 requires a high density of CD4 on the surface of the cell, marking the CD4⁺ T helper cell as its primary target cell. As noted above, fusion of the viral and host membranes requires the presence of the primary surface receptor, CD4, and one of two secondary surface receptors, usually CCR5 or sometimes CXCR4, two chemokine receptors that are found on a subset of cells. Engagement with the coreceptor exposes the hydrophobic gp41 fusion peptide, which then inserts into the host cell membrane. Insertion of each gp41 in the trimer brings the virus in even closer proximity to the host cell membrane; gp41 then forms a hairpin mediated by two helical domains in the protein, and since gp41 is in a trimer this results in a six helix bundle. This six helical bundle serves as the driving force behind membrane fusion by bringing the membranes close enough to form a fusion pore through which the virus can release its capsid into the cytosol of the host cell where viral DNA synthesis can begin. The need for a high density of CD4 for efficient entry and the use of CCR5 as the coreceptor make the predominant form (and the transmitted form) of the virus appropriately called HIV-1 R5 T cell-tropic.

Uncoating, Reverse Transcription, Nuclear Localization, and Integration

Following release of the viral capsid into the host cell cytoplasm, the capsid core begins to uncoat, although the extent to which the p24 CA capsid protein is released is unclear. The partially uncoated core utilizes the host cytoskeletal network to traffic toward the host cell nucleus. Inside the viral capsid core, reverse transcriptase (RT) begins converting the single-stranded viral RNA into dsDNA, with DNA synthesis being primed initially using a host cell tRNA that was earlier packaged into the virion and placed near the 5' end of the RNA genome (**Fig. 3**). Linear, double-stranded DNA is fully synthesized in the cytoplasm. This replication complex contains integrase, and while in the cytoplasm the integrase protein removes 2 bases from each 3' end of viral DNA in preparation for integration in the nucleus, making the pre-integration complex (PIC).

Once reaching the nucleus the PIC is transported across the nuclear membrane through the nuclear pore complex, in part mediated by interactions with residual CA protein. Inside the nucleus the PIC associates with host factors (such as LEDGF) that target the PIC to transcribed regions of the viral genome. These host factors help direct integration to regions of the host genome where the viral genome will be more likely to be transcribed. After interacting with the host chromatin, the integrase protein cleaves the host DNA and, in a strand transfer reaction, covalently links the viral DNA to the host DNA where it can be transcribed by the host transcription machinery (**Fig. 3**).

Fig. 3 Early phase of the HIV-1 life cycle. HIV-1 begins its life cycle by binding to its primary receptor CD4 and then its secondary receptor CCR5 (shown) or CXCR4 to facilitate membrane fusion. In the cytoplasm there is some level of “uncoating” to form the Reverse Transcription Complex (RTC) where reverse transcription of the viral RNA genome occurs while making its way to the nucleus using a vast array of microtubule networks. After completion of DNA synthesis the viral DNA is associated with integrase forming the Pre-Integration Complex (PIC), which moves through nuclear pore complex (NPC) to traverse the nuclear membrane. The PIC migrates to a host chromosome where integration occurs. Figure adapted from Campbell, E.M., Hope, T.J., 2015. HIV-1 capsid: the multifaceted key player in HIV-1 infection. *Nature Reviews Microbiology* 13, 471–483. with permission.

Late Phase

Gene Expression and Assembly

After integration, sequences in the LTR are recognized by host RNA polymerase II to synthesize viral RNA. However, initially the resulting transcripts are short and prematurely terminated, with only a small fraction being full length genomic RNA. The fraction that is full length is spliced by the host cell machinery initially to give mRNAs for Tat, Rev, and Nef. Tat recruits a host transcription factor complex P-TEFb with Tat binding to an RNA hairpin in the short transcript (TAR). Bringing P-TEFb close to the host RNA polymerase II leads to modification of the polymerase to allow more of the transcripts to be full length (i.e., making the polymerase more processive).

Normally mRNAs have to be fully spliced to leave the nucleus. However, HIV-1 gene expression requires the use of partially spliced or even unspliced RNA (the form of genomic RNA). To accomplish this the viral Rev protein binds to another large RNA hairpin within the D4-A7 intron in the *env* gene. Rev links partially spliced and unspliced viral RNA to a different nuclear export pathway, mediated by the host protein Crm1, such that the RNA avoids the quality control the host applies to RNAs going through the mRNA nuclear export pathway. Over 40 RNA transcripts are generated from the full length viral genomic RNA transcript by alternate splicing patterns, which allow expression of all of the viral proteins and full length RNA for packaging into new virions.

As noted above, some of the viral proteins function to manipulate the host cell (Tat, Rev, Nef, Vif, Vpr, Vpu) while others are used to make new virion particles. The Env protein migrates through the ER/Golgi apparatus of the cell to get to the cell surface/plasma membrane (Fig. 4). The Gag and Gag-Pro-Pol proteins are synthesized in the cytoplasm but are targeted to the inner face of the cell surface/plasma membrane. The Gag protein alone is sufficient to mediate budding of a particle from the cell membrane (with Gag-Pro-Pol being mixed in at a 1–20 ratio). The Env protein interacts with the N-terminal domain of Gag (the MA domain) to increase its incorporation into budding virion particles.

Fig. 4 Late Phase of the HIV-1 life cycle. Following integration, the HIV-1 genome is transcribed into full length RNA followed by complete splicing to produce Tat and Rev, which increase the level of expression and allow for unspliced and partially spliced RNAs needed for virion assembly and to function as mRNA for the structural proteins. HIV-1 Env is processed and trafficked to the host cell membrane via the secretory pathway (ER and Golgi) while Gag, with some bound to full length viral RNA, and Gag-Pro-Pol (here called GagPol) migrate through the cytoplasm toward the host cell membrane to form an immature, budding viral lattice. Membrane fission and release of the newly assembled virion from the host cell is mediated by ESCRT I, ESCRT-III, and ALIX proteins, and maturation of the virion is dependent on viral protease cleavage of Gag and Gag-Pro-Pol into their respective proteins. Figure adapted from Freed, E.O., 2015. HIV-1 assembly, release and maturation. *Nature Reviews Microbiology* 13, 484–496. with permission.

Budding and Maturation

As a Gag lattice forms at the surface of the plasma membrane it creates a budding structure. However, the particle must undergo membrane fission to be released from the host cell in the form of an immature virion. Host proteins in the ESCRT pathway target the C-terminal domain of Gag (p6) to mediate this membrane fission allowing the enveloped virus to detach from the cell (Fig. 4). During this budding process, the viral protease PR dimerizes in the Gag-Pro-Pol precursor to become active, first cleaving itself out then cleaving the Gag and Gag-Pro-Pol precursor polypeptides into their respective proteins to initiate the maturation of the virion into its infectious form with its familiar cone-shaped capsid core.

Fig. 5 HIV-1 global subtype distribution and 2019 UNAIDS statistics. Countries forming a region are shaded in the same color on the world map. The surface area of each pi-chart corresponds to the total number of people living with HIV-1 in each region. CRF = circulating recombinant form. URFs = unique recombinant forms. Figure adapted from Hemelaar, J., Elangovan, R., Yun, J., *et al.*, 2018. Global and regional molecular epidemiology of HIV-1, 1990–2015: A systematic review, global survey, and trend analysis. The Lancet Infectious Diseases 19, 143–155. with permission.

2019 UNAIDS HIV Statistics
37.9 million people living with HIV
23.3 million people had access to ART
1.7 million people became newly infected
770,000 died from AIDS-related illness
90-90-90 Initiative
79% living with HIV knew their status
78% of those aware of their status were receiving treatment
86% of those receiving treatment were virally suppressed
At Risk Populations
Men who have sex with men (22 times more likely)
Injection drug users (22 times more likely)
Sex workers (21 times more likely)
Transgender people (12 times more likely)

Epidemiology

Currently we recognize distinct lineages of HIV-1 called subtypes or clades (designated subtypes A, B, C, etc. and also called subgroups; Fig. 5) which are all part of the M group. Virus isolates within a subtype are more similar at the sequence level than they are to virus isolates in different subtypes. We interpret the existence of these subtypes as the result of having a diverse (in sequence composition) population of viruses within the human population within western Africa around 60 years ago. The virus then spread in single transmission events to different areas of the world, creating a sequence or genetic bottleneck that defined the subsequent expansion of that virus in these different places. These are all strains of HIV-1 with either little or no biological differences but we can still see the evidence of the genetic bottleneck coming to North America for example, where we have viruses that are related to each other and called subtype B (or clade B), the same predominant viral lineage that is found in western Europe. We can see subtypes A and D in eastern Africa, and another jump occurred subsequently to create another A subtype cluster from the east African virus in eastern Europe. Subtype C virus entered southern Africa then spread through India and into China. These are broad stroke descriptions of the early spread of the virus into the larger human population. Where two subtypes are circulating in the same human population it is possible for a person to become infected with both subtypes where recombinant genomes between the two viruses can occur and get transmitted, making the inference of its history more difficult. In addition, as people have moved between different regions of the world over the years the different lineages of viruses have become more mixed.

Modes of Transmission and Risk Factors

The modes of HIV-1 transmission are well-defined. HIV-1 can be transmitted through sexual activity, exposure to blood, and from mother to child during pregnancy, birth, and breast feeding. There are six bodily fluids by which HIV-1 transmission can occur, including blood, semen, pre-semen, vaginal secretions, anal secretions, and breast milk. Additionally, there are four common routes of transmission that include the vagina, the tip of the penis, anus, and open sores (especially in the genital tract). In general, exposure of mucosal surfaces to virus-containing fluids creates the risk of transmission. There is no epidemiological data to suggest that HIV-1 transmission can occur via exchange of saliva (kissing, sharing drinks and food) or mosquito bites, mostly because the virus is unable to reach transmissible titers in these fluids.

Unprotected sexual contact is the primary mode of transmission worldwide. HIV-1 has a relatively low rate of transmission, with transmission rates at least 10–100 times less per sexual encounter than other sexually transmitted infections (STIs) such as gonorrhea, chlamydia, and syphilis. However, there are numerous factors that can enhance infectivity of the source partner such as a high viral load, other STIs (in either partner), and blood contact during sex. The probability of transmission increases with the likelihood of microtrauma during sexual contact and direct exposure of blood to infected fluids (Table 1).

Outside of sexual contact, another common mode of transmission is through exposure of HIV-infected blood via injection drug use. Sharing of needles with HIV-contaminated blood has the highest rate of transmission of any exposure, aside from blood transfusion with HIV+ blood which has a transmission rate of essentially 100%. Mother-to-child transmission can take place

Table 1 Estimated per-act risk for acquisition of HIV-1, by exposure route

Exposure route	Risk per 100 exposures to an infected source
Blood transfusion	90
Needle-sharing injection-drug use	0.67
Percutaneous needle stick	0.3
Receptive anal intercourse	0.5
Receptive penile-vaginal intercourse	0.1
Insertive anal intercourse	0.065
Insertive penile-vaginal intercourse	0.05
Receptive oral intercourse	0.01
Insertive oral intercourse	0.005
Mother-to-child transmission (without breast-feeding)	30
Breast-feeding for 18 months	15

during pregnancy, during delivery, and during breastfeeding, although this transmission risk is essentially reduced to zero if the mother is on suppressive antiviral therapy.

Prevalence

HIV-1 has been detected in every region of the world. Currently it is estimated that 37.9 million people are living with HIV. In 2019, 1.7 million people became newly infected and 770,000 died from AIDS-related illnesses (**Fig. 5**). Fortunately, 23.3 million individuals had access to antiretroviral therapy (ART), and this number will only continue to rise with global initiatives to increase sexual health education and access to treatment.

The prevalence of HIV-1 varies globally, disproportionately affecting Sub-Saharan Africa. Eastern and Southern Africa contain ~60% of the total global infections, with Asia and the Pacific (15%), West and Central Africa (13%), Latin America (2%), the Caribbean (0.9%), the Middle East and North Africa (0.6%), Eastern Europe and Central Asia (4%), and Western/Central Europe and North America (5%) comprising the other ~40%. Prevalence is not uniform across the population in these regions. Both engaging in acts that can mediate transmission and the level of pre-existing infection within the subgroup where these acts are shared have led to significantly elevated levels of infection among certain subgroups of people, which has led to focused efforts in treatment and prevention within these subgroups.

Diagnosis

A diagnosis of an HIV-1 infection is made based on one of three different measures. Most commonly the diagnosis is made based on the host antibody response to the virus. By examining a group of people with suspected time of exposure it is possible to determine that a person becomes antibody positive in an ELISA (enzyme-linked immunosorbant assay) test around 22 days after transmission. This test is usually confirmed with a Western Blot test where viral proteins transferred to a thin membrane are bound by host antibodies and the presence of the bound antibodies detected. While these tests are usually done using a sample of blood, antibodies are also shed into saliva which has allowed a “rapid test” to be developed based on a saliva sample to test for the presence of HIV-specific antibodies, although this test becomes positive later than the antibody blood test.

The detection of antibodies is a measure of the host response to the replicating virus. The two other tests are designed to measure the presence of the virus itself. Virus is replicating in the body before the antibody response appears. Thus detection of the virus itself offers the possibility for detection of the infection even before the appearance of the host antibody response. The two tests that are used are a sensitive ELISA assay to detect the viral capsid protein (CA/p24), and a PCR-based assay to detect the presence of viral RNA. Most people who get infected are initially infected with a single or a few virus particles that then start replicating in the new host. Very early after infection there is not enough virus to measure with these methods so for about 7–10 days there is a period called the eclipse phase where the viral infection can’t be seen by any of these tests. The detection of viral RNA in the blood is the most sensitive test and the first to be positive after the eclipse phase, followed within a week by the ELISA test for viral capsid protein, followed by one week for the detection of viral antibodies. In the initial absence of an immune response the virus multiplies rapidly, reaching a peak level of viremia in the blood at about 3 weeks. With the onset of the host immune response the virus is partially controlled and brought down to a “set point”, measured as copies of viral RNA per milliliter of blood (usually in the range of 10,000 to 100,000 copies of viral RNA per milliliter). This level of viral RNA is relatively constant or trends upward over time and represents a steady-state level of viral replication and the death of infected cells over time.

Table 2 *AIDS Defining Illnesses.* There are a set of illnesses often associated with HIV-1 infection and the onset of AIDS. These range from bacteria and other viral infections to virus-induced cancers. This is the list of AIDS defining illnesses as designated by the U.S. Center for Disease Control

AIDS-defining illnesses

Bacterial infections (recurrent)	Kaposi sarcoma
Candidiasis of bronchi, trachea, or lungs	Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex
Candidiasis of esophagus	Lymphoma, Burkitt
Cervical cancer	Lymphoma, immunoblastic, primary brain
Coccidioidomycosis, disseminated or extrapulmonary	Mycobacterium avium complex or Mycobacterium kansasii, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary	Mycobacterium tuberculosis of any site, pulmonary, disseminated, or extrapulmonary
Cryptosporidiosis, chronic intestinal	Mycobacterium, other species or unidentified species, disseminated† or extrapulmonary
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age > 1 month	Pneumocystis jiroveci pneumonia
Cytomegalovirus retinitis (with loss of vision)	Pneumonia, recurrent
Encephalopathy, HIV related	Progressive multifocal leukoencephalopathy
Herpes simplex: chronic ulcers (> 1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age > 1 month)	Salmonella septicemia, recurrent
Histoplasmosis, disseminated or extrapulmonary	Toxoplasmosis of brain, onset at age > 1 month
Isosporiasis, chronic intestinal (> 1 month's duration)	Wasting syndrome attributed to HIV

Source: Schneider, E., Whitmore, S., Glynn, K.M., *et al.*, 2008. Revised surveillance case definitions for HIV infection among adults, adolescents, and children aged < 18 months and for HIV infection and AIDS among children aged 18 months to < 13 years—United States, 2008. MMWR Recommendations and Reports 57 (RR-10), 1–12.

Once a person becomes positive for anti-HIV-1 antibodies they will remain antibody-positive for life. However, combination antiretroviral therapy (see below) can fully suppress viral replication such that the clinical tests for viral RNA and viral capsid protein become negative. For HIV-1, even though these two measures of virus turn negative the virus is still present in a latent state, and for most people the virus will "rebound" in the blood within 2–4 weeks if antiviral therapy is stopped. Thus people with HIV-1 must initiate life-long therapy to stop viral replication (and disease progression) and keep the virus from reappearing in the blood.

Clinical Features

There is an early feature of infection with HIV-1 that occurs shortly after transmission, although its frequency varies greatly among different cohorts. About 2–4 weeks after infection there can be transient flu-like symptoms associated with the initial host immune response. As the viral load is brought down to its set point these symptoms resolve. When symptoms appear at this stage they are referred to as acute infection syndrome.

As these early symptoms resolve, a person transitions into a state of clinical latency where the virus is replicating and damaging the immune system but not yet to a point where symptoms occur. It is the cumulative damage to the immune system that leads to the defining feature of an HIV-1 infection, i.e., immunodeficiency. In the absence of antiviral treatment, there is an ongoing loss of CD4⁺ T cells in the body, a cell type that is central to coordinating the host immune response. As the CD4⁺ "helper" T cells are lost (we start with around 1000 such cells per microliter of blood) the host becomes increasingly susceptible to infections from other viral, bacterial, and fungal agents as well as virus-induced cancers (Table 2). Ultimately it is these other infectious agents or tumors that lead to death. The clinical state of immunodeficiency is defined as the appearance of one of these opportunistic infections or when the CD4⁺ T helper cell count drops below 200 cells per microliter in the blood (which defines a state of enhanced risk of opportunistic infection).

Two features of this process are highly variable. Some people progress rapidly to a state of immunodeficiency (1–2 years) while others progress slowly (15–20 years) or not at all, there being a small group of people (1%) who have a very low set point with no evidence of disease progression. Overall the average time from infection to the onset of immunodeficiency is in the range of 8–10 years.

The other feature that is highly variable is what happens as a person becomes immunodeficient. Some of the infections are acquired from our environment and are agents that we are exposed to regularly but control in an immunocompetent state. Others are agents that we are already infected with and normally control in a latent state but then cannot. A person experiences only a subset of these infections but we have little understanding why the passage into an immunodeficient state can have such varied consequences. However, individually or together these infections present serious challenges for the body. Under certain circumstances HIV-1 itself may become the opportunistic infection. In untreated infection a condition named AIDS-associated dementia ensues that involves replication of the virus within the central nervous system and the adaptation of the virus to that environment.

In this case the virus expands from replication in blood and lymphoid cells into the CNS where it is associated with a distinct clinical outcome.

Pathogenesis

There is one overarching principle in HIV-1 pathogenesis - the virus infects and kills CD4⁺ T cells and these cells are lost over time until a state of immunodeficiency is reached. It is tempting to make viral infection and loss of these cells the sum total of viral pathogenesis. However, there are many complex changes in the body that occur over the course of an untreated infection and it has been difficult to determine whether these ancillary changes contribute to pathogenesis or are the result of the immunodeficient state induced by the cumulative loss of CD4⁺ T cells. For example, it appears that too few CD4⁺ T cells are infected and killed by the virus to account for the magnitude of loss of these cells over time. Thus there have been studies of “standby” effects where other mechanisms contribute indirectly to the loss of CD4⁺ T cells and thus ultimately contribute to the immunodeficient state. Ideas that have been explored include a loss of the ability to produce new CD4⁺ T cells after years of ongoing replacement, loss of normal architecture in lymphoid tissue where most T cells reside, and local effects where cells near an infected cell also die.

Even the mechanism of how an infected cell dies is unclear. The viral protein Vpr induces cell cycle arrest which precludes the cell from dividing. The viral Env protein may continue to bind its CD4 protein receptor in the infected cells inducing aberrant signaling (several viral proteins down regulate CD4, perhaps for this reason). Budding of viral particles from the cell's plasma membrane could cause loss of membrane integrity. Virus replication may induce one of several “cell death” pathways within the cell.

Viral evolution within an infected person is a key feature of viral pathogenesis. The virus replicates every one to two days within a cell and then must jump to a new target cell to continue replicating. At steady-state (i.e., with a constant set point) one new cell is infected for each cell that dies. If the immune system were fully competent we might expect it to win over the virus and clear the virus from the body, as happens with most RNA viruses (such as influenza virus). In contrast, HIV-1 sustains replication in the face of an active immune response. It is possible that the virus blunts the host immune response specifically as the virus replicates most efficiently in activated cells, such as those CD4⁺ T cells responding to HIV-1 itself. Given the impaired host response, the virus is able to maintain a sufficiently large population size that, with its short replication time and relatively error prone replication apparatus, allows sequence diversity to accumulate in the viral population. Out of this diverse population variants that are able to escape the host's targeted immune response grow out, and this process is repeated over the course of the infection as the host response changes and the virus continues to evolve.

Broadly, there are two types of adaptive (specific) immune responses the host mounts: CD8⁺ T cells can target short sequences in viral proteins that are distributed among all of the viral proteins as they are “presented” on the surface of an infected cell (recognized as foreign resulting in the killing of that cell); alternatively antibodies target the surface proteins of the virus particle, for HIV-1 this is the Env protein. Since the Env protein is the target of both CD8⁺ T cells and antibodies this explains why this protein is the most variable in the viral population, undergoing the most evolution to escape both arms of the host immune response.

Viral evolution plays a role in several other features of replicating virus beyond immune escape: expansion of the host range of cell types that can be infected, and the evolution of drug resistance. In expanding its host range HIV-1 goes through distinct evolutionary pathways for its use of both its receptor CD4 and its chemokine coreceptor.

Coreceptor Switch

The predominant form of HIV-1 uses the host chemokine receptor CCR5 as its coreceptor. Late in disease as the CD4⁺ T cell population is lost the probability of encountering a preferred target cell decreases. Under these circumstances there is selective pressure to be able to replicate in a different cell type. There is a subpopulation of CD4⁺ T cells that express CXCR4 but not CCR5. HIV-1 evolves to be able to use CXCR4 as its coreceptor thus expanding the number of cell types it can infect. Such viruses are typically seen late in untreated disease and correlate with more rapid disease progression, although it is not known if this is because of the expanded host range or as an indirect marker of the loss of CD4⁺/CCR5⁺ T cells. The coreceptor switch involves evolution of sequences within the viral Env protein, which is responsible for interacting with the coreceptor during viral entry.

Macrophage-Tropic HIV-1 and Infection of the CNS

One of the important AIDS-defining illnesses that became apparent shortly after the AIDS syndrome was identified was HIV-associated dementia (HAD), which appears in about 25% of people with untreated infections. The appearance of HAD focused attention on a potential role for HIV-1 in infection of the central nervous system (CNS). The brain/CNS is somewhat immune privileged and as a result there are not very many CD4⁺CCR5⁺ T cells to support infection. However, there are two other cell types in the CNS that express CD4 and CCR5: the endogenous myeloid cell microglia and inflammatory macrophages that have trafficked across the blood-brain barrier into the CNS (perivascular macrophages that appear around blood vessels in the brain). However, there is one big and important difference with these cell types compared to CD4⁺ T cells, the density of CD4 on

microglia and macrophages is about 25 times lower than it is on T cells. As a result, the normal form of HIV-1 (R5 T cell-tropic) is very inefficient at infecting these myeloid cells. This leads to the second evolutionary pathway to expand the host range of infected cells - evolution to efficiently use a low density of CD4 for entry, which we associate with macrophage tropism (R5 M-tropic). There are claims that HIV-1 can infect yet another cell type in the brain, astrocytes, although this is hard to reconcile with the fact that astrocytes do not express the viral receptor CD4.

While CD4⁺ T cells are not abundant in the CNS they are always trafficking from the blood at a low level and can be found in cerebral spinal fluid (CSF). Some of these cells are infected thus the brain is constantly being exposed to virus that is equivalent to the virus in the blood (R5 T cell-tropic). It has been hypothesized that monocytes can carry virus into the CNS, where they differentiate into tissue macrophages. However, the low density of CD4 on monocytes in the blood makes these cells poor targets for infection by the R5 T cell-tropic form of the virus found in blood. Thus trafficking CD4⁺ T cells seem like the more likely culprit for introducing virus into the CNS.

While the CNS gets exposed to virus in all people via infected T cell trafficking, it is only in a subset of people where there is detectable replication of HIV-1 in the CNS. There appears to be little movement of virus from the CNS back to the blood (at least that is detectable), thus when virus starts replicating in the CNS it appears as a new genetic lineage of the virus that is distinct from the virus in the blood. This is called a compartmentalized viral population. In the case of the CNS this is usually associated with the ability to use CD4 more efficiently for entry, i.e., the evolution of macrophage tropism. Between 10% and 20% of people have evidence of virus growing in the CNS within the first two years of untreated infection (seen as genetically compartmentalized virus in the CSF compared to the blood). This rises to 40% of people in late stage untreated infection, and includes most of the people who are diagnosed with HAD. An active area of research is determining the extent to which virus can persist in the CNS during suppressive antiretroviral therapy.

HIV-associated dementia represents the end-stage of CNS pathogenesis, however it is now clear there is a broader spectrum of CNS-related disease states that can be measured and are collectively called HIV-associated neurocognitive defects (HAND). HAND is subclassified in the clinic based on symptomatic presentation and severity as either Asymptomatic Neurocognitive Impairment (ANI), Mild Neurocognitive Disorder (MND), or the most severe HIV-associated Dementia (HAD). These states are seen in people with untreated infections but there is concern that time spent untreated either leaves a person in one of these states even after therapy starts or makes it more likely they will progress even while on therapy. For people on antiretroviral therapy, the frequency of HAD has greatly decreased, occurring in only 2%–8% of treated people; however, ANI and MND have a prevalence of 30% and 20%–30%, respectively. As a general rule drugs are not efficient at crossing the blood-brain barrier leaving drug concentrations suboptimal in the CNS. With less potent drugs a phenomenon of CNS escape has been seen where virus is replicating within the CNS, sometimes with associated symptoms, while being suppressed in the blood. This is less of a problem with the recent more potent regimens.

Evolution of Drug Resistance

With a large population size of virus within the host, a rapid rate of replication (300 times per year), and an error prone DNA polymerase (reverse transcriptase, about 1 nucleotide substitution in every three genomes synthesized), the virus generates a lot of sequence diversity. Most nucleotide substitutions (mutations) are deleterious and are lost from the population, but they are constantly reappearing with the error prone polymerase. However, as selective pressures change then minor variants in the population may suddenly become more fit and grow out. This is the case with drug resistance. If drug concentration or potency is too low and allows continued viral replication then resistant variants will be selected causing the drugs to lose potency. The success of highly potent drug regimens is that they quickly shrink the size of the pool of replicating virus which blocks the evolution of drug resistance to multiple drugs at one time. Ironically, the same three drugs that together block viral replication in a typical antiretroviral regimen, if given sequentially would simply select for resistance.

Latency

Even when viral replication is completely blocked by suppressive therapy (see below), HIV-1 can persist in the body, referred to as a latent infection. In this state the virus exists as integrated DNA that is not transcribed. Expression of viral DNA into RNA and virus particle release happens stochastically. When suppressive antiviral therapy is present this transiently expressed virus cannot replicate and is lost. However, if therapy is discontinued this low level of stochastically released virus restarts the systemic infection. Latently infected cells appear to be a biological accident but with significant consequences. The virus has no "program" to become latent, its goal is to replicate as fast as possible. Thus when therapy almost clears all of the infected cells it is only a small number of long-lived cells that got infected but are not expressing the viral genome that accidentally create this reservoir. However, this latent reservoir decays so slowly that it is present for the entire life of the infected person. There is great interest in the research community to find ways of removing this latent reservoir so that a person could stop taking antiretroviral therapy and not experience reappearance of the virus. This has been accomplished several times in the context of an allogeneic transplant of blood cells in the context of cancer therapy where the patient was given new blood cells from a donor who had both copies of their CCR5 gene mutated, making their new transplanted CD4⁺ T cells resistant to infection. While this represents a "proof-of-concept" for an HIV-1 cure, this treatment is too extreme to use in the general population.

Table 3 FDA approved antiretrovirals for the treatment of HIV-1 infection. There are currently six classes of drugs approved for the treatment of HIV-1 infection, including Non-Nucleotide Reverse Transcriptase Inhibitors, Nucleotide Reverse Transcriptase Inhibitors, Protease Inhibitors, Fusion Inhibitors, Entry Inhibitors, and Integrase Inhibitors. Another drug class worthy of noting is Latency Reversing Agents, which aim to activate viral expression in latently infected cells to allow immune-mediated clearance, but these agents are still being investigated in the clinic and have yet to be approved by the FDA for the treatment of HIV-1

Nucleoside reverse transcriptase inhibitors		Protease inhibitors	
Brand name	Generic name	Brand name	Generic name
Combivir	lamivudine and zidovudine	Agenerase	amprenavir, APV (no longer marketed)
Emtriva	emtricitabine, FTC	Aptivus	tipranavir, TPV
Epivir	lamivudine, 3TC	Crixivan	indinavir, IDV,
Epzicom	abacavir and lamivudine	Fortovase	saquinavir (no longer marketed)
Hivid	zalcitabine, dideoxycytidine, ddC	Invirase	saquinavir mesylate, SQV
Retrovir	zidovudine, azidothymidine, AZT, ZDV	Kaletra	lopinavir and ritonavir, LPV/RTV
Trizivir	abacavir, zidovudine, and lamivudine	Lexiva	Fosamprenavir Calcium, FOS-APV
Truvada	tenofovir disoproxil fumarate and emtricitabine	Norvir	ritonavir, RTV
Videx EC	enteric coated didanosine, ddl EC	Prezista	darunavir
Videx	didanosine, dideoxyinosine, ddl	Reyataz	atazanavir sulfate, ATV
Viread	tenofovir disoproxil fumarate, TDF	Viracept	nelfinavir mesylate, NFV
Zerit	Stavudine, d4T	<i>Fusion inhibitors</i>	
Ziagen	abacavir sulfate, ABC	Fuzeon	enfuvirtide, T – 20
<i>Nonnucleoside reverse transcriptase inhibitors</i>		<i>Entry inhibitors</i>	
Edurant	rilpivirine	selzentry	maraviroc
Intelence	etravirine	<i>Integrase inhibitors</i>	
Rescriptor	delavirdine, DLV	Isentress	raltegravir
Sustive	efavirenz, EFV	Tivikay	dolutegravir
Viramune	nevirapine, NVP	Vitekta	elvitegravir

Treatment

The current standard of care for people living with HIV is combination antiretroviral therapy, or ART. Over a 15-year period we went from the identification of HIV-1 as the cause of AIDS (early 1980s) to the identification of the first active drug (AZT, late 1980s), to the discovery of potent three drug regimens capable of suppressing viral replication and stopping the disease course (late 1990s). Over the last 20 years drug potency has continued to increase and newer formulations allow drug delivery to become increasingly convenient, now one pill once a day for most people. Modern regimens allow people to live a near normal life with a full expected life span. However, HIV-1 is maintained as a latent infection even in the face of inhibitors that block all viral replication. This results in the need to take antiretroviral therapy throughout life since stopping typically results in the rebound/reappearance of high levels of replicating virus in less than a month. There are four main classes of antiretrovirals used to treat HIV, each targeting a different stage of the virus life cycle. These include: Entry Inhibitors, Reverse Transcriptase Inhibitors, Protease Inhibitors, and Integrase Inhibitors. A full list of current FDA-approved drugs for the treatment of HIV-1 can be found in [Table 3](#).

Entry Inhibitors

Entry inhibitors block entry of the virus into the cell. One type of entry inhibitor binds to the host cell coreceptor CCR5 preventing its interaction with the viral Env protein (e.g., maraviroc) thus blocking the transition to the membrane fusion function of gp41. Another drug (enfuvirtide) is a peptide mimetic of a portion of the gp41 sequence that binds to block formation of the six helix bundle, thus preventing fusion. As a peptide this particular drug must be injected and thus is used only infrequently in people who have virus that is extensively drug resistant to other regimens.

Reverse Transcriptase Inhibitors

Reverse Transcriptase Inhibitors (RTIs) target the viral DNA polymerase reverse transcriptase, which is packaged in the virus particle and is responsible for reverse transcribing the single-stranded viral RNA genome into double-stranded DNA in the newly infected cell. RTIs can be subdivided into two classes, nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). NRTIs are nucleoside or nucleotide analogs that are missing the 3'-OH on the ribose. This OH- is used to extend the growing DNA chain as each nucleotide precursor is added. Thus when one of the NRTIs gets incorporated into the growing viral DNA chain it terminates synthesis since the growing point now cannot get extended with the

next nucleotide. NNRTIs are non-nucleoside analogs that bind in a pocket in RT to allosterically prevent enzymatic activity. NRTIs commonly comprise two-thirds of the three-drug cocktail prescribed as ART, with the third drug historically being a boosted protease inhibitor, an NNRTI, or more recently an integrase inhibitor.

Protease Inhibitors

Protease Inhibitors (PIs) bind the active site of the viral protease, which is responsible for cleaving the HIV-1 polyproteins, namely the Gag and Gag-Pro-Pol precursors, into their mature and active protein domains. Protease inhibitors are peptide mimetics of the cleavage sites present in the precursor proteins. Inhibition of the viral protease prevents maturation of the viral proteins, leaving virions in either an immature state or a state of mixed processed and unprocessed proteins which results in a noninfectious virion. An early PI (ritonavir) had the fortuitous property of binding and inhibiting the enzyme responsible for its clearance, cytochrome P450-3A4, and in so doing greatly extended the half-life of the drug in the body. Ritonavir (or another drug with similar properties) is now often given in lower doses as a "booster" to increase the half-life of other drugs in the regimen that are metabolized by P450-3A4.

Integrase Inhibitors

Integrase has a series of conserved acid amino acids that coordinate the binding of a Mg^{2+} ion through an acidic and polar amino acid interface. This interface orients the Mg^{2+} ion allowing it to be involved in a nucleophilic attack of a host DNA phosphodiester bond by the viral 3' hydroxyl, resulting in integration of viral DNA into the host DNA via a strand transfer reaction. Integrase strand transfer inhibitors, or ISTIs, bind to the same Mg^{2+} to get oriented within the active site to inhibit the strand transfer reaction and, consequently, integration. ISTIs have recently emerged as the drug of choice over boosted protease inhibitors and NNRTIs in most ART regimens due to their increased potency, which results in less undesirable side effects and a lower probability that the virus will develop resistance mutations.

Prevention

Of the 37.9 million people currently living with HIV-1, approximately 60% are currently receiving ART. Further, the percentage of people living with HIV-1 and on ART is expected to continually rise as governments and health organizations around the world increase efforts to achieve the '90-90-90 Goal', an initiative from the World Health Organization that aims to have 90% of all infected individuals aware of their status, 90% of those aware of their status administered ART, and 90% of those administered ART to be virally suppressed. While diagnosis, treatment, and adherence are each crucial elements for controlling the HIV-1 epidemic, prevention efforts will also contribute significantly to making the 90-90-90 initiative successful. In this regard, Treatment as Prevention (TasP) has been one of the most effective prevention strategies in that people who are successfully suppressed on therapy have essentially a zero chance of transmitting the virus.

Biomedical Prevention

Biomedical intervention is key to preventing the transmission of HIV-1 and further controlling the epidemic. There are numerous biomedical interventions that have been shown to decrease the rate of transmission. For example, circumcision has been shown to decrease a male's risk of acquiring HIV-1 by 50–60%. HIV-1 prevalence tends to be higher in countries where male circumcision at birth is not standard medical practice. Thus, encouraging voluntary male circumcision could potentially prevent a significant number of new infections, if there was significant uptake. Additionally, female-oriented prevention strategies such as ART-containing vaginal gels as prophylaxis have been shown to decrease transmission rates up to 54% in clinical trials, although equivalent real-world efficacy of these gels has been harder to realize.

For many viral diseases there is a vaccine that allows control of virus spread and is associated with a reduced disease course. The development of a vaccine for HIV-1 has proven to be especially challenging. One large trial showed about 30% efficacy in preventing infection, enough to inspire hope that there may be a path forward but too low to be useful in its current form. The search for an HIV-1 vaccine is currently driving an intense effort to understand how the body interacts with foreign antigens and to define how best to deliver these antigens to the immune system.

What is PrEP?

The idea of Pre-Exposure Prophylaxis, or PrEP, as a prevention strategy grew from the observation that HIV-infected women on ART rarely transmit to their offspring during birth, as long as the women are virally suppressed. PrEP is treatment with anti-retrovirals prior to exposure to decrease the risk of acquiring HIV-1 if exposed. During acute infection, HIV-1 first replicates in

mucosal tissue at the point of entry, such as the genital or rectal tract. The presence of antiretroviral drugs in these tissues prevents the initial replication of the virus leaving the person uninfected. PrEP typically includes one or two antiretroviral drugs rather than the three used for suppressive treatment of an infection. The ongoing development of long acting drug delivery systems (lasting weeks to months) is likely to have a significant impact on the uptake of PrEP in people at increased risk of exposure to HIV-1. Another new line of prevention research is to use broadly neutralizing monoclonal antibodies to neutralize incoming virus at exposure. If such an approach proves efficacious then genes for these antibodies could potentially be introduced using gene therapy vectors so that each person will be able to make these antibodies over an extended period of time.

Social and Educational Prevention

While biomedical interventions are crucial tools for preventing HIV-1 transmission, there will continue to be an important role for social and educational prevention initiatives. It is clear that greater access to information regarding sexual health and safe sex practices, reducing risk associated with sharing injection equipment, and knowledge about basic HIV-1 transmission biology can significantly impact transmission rates.

In countries such as Zimbabwe, Uganda, Zambia, Malawi, Kenya, and Thailand, initiating behavioral interventions has been successful in decreasing transmission rates. Particularly, improved sexual education courses, more thorough and informed HIV-1 testing and counseling, and well-organized, state-run prevention programs such as Thailand's '100% Condom' program, which promotes the use of condoms in sex work, have contributed to a decline in transmission. Unfortunately, many of these programs have yet to fully reach at-risk populations. Stronger political representation and funding opportunities will be crucial for expanding existing programs and creating new programs to aid these important populations. Ultimate success in fully controlling the HIV-1 epidemic will likely require some level of success in using all of these different approaches to prevention.

Human Metapneumovirus (*Pneumoviridae*)

Antonella Casola, Matteo P Garofalo, and Xiaoyong Bao, The University of Texas Medical Branch, Galveston, TX, United States

© 2021 Elsevier Ltd. All rights reserved.

Glossary

Capping Addition of a guanosine nucleotide to the 5'-end of mRNAs, which is then methylated by a methyl transferase.

Glycosaminoglycan Long, unbranched, highly negatively-charged polysaccharides that consist of repeating disaccharide subunits that are located on the cell surface, or in the extracellular matrix.

Lipid raft Membrane microdomains enriched in cholesterol and sphingolipids that modulate the membrane distribution of receptors and signaling molecules.

PAMP Molecules (lipids, proteins, nucleic acids) derived from invading pathogens that trigger specific receptor-mediated host responses.

RDG Peptide motif responsible for protein interaction with adhesion proteins called integrins.

Ribavirin A nucleoside analog (1-beta-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) that has antiviral activity against a number of RNA viruses, including hMPV.

Syncytium A multinucleated cell, formed by fusion of the plasma membrane of an infected cell with those of its neighbors.

Transcriptional elongation Process through which nucleotides are added to a growing RNA chain during gene transcription.

Classification

Human metapneumovirus (hMPV) is a non-segmented, negative-sense (–), single-stranded RNA (ssRNA) virus, formerly a member of the *Paramyxoviridae* family. In 2016 it was reclassified into the family *Pneumoviridae* of the order *Mononegavirales*. This new family consists of two genera, *Metapneumovirus* and *Orthopneumovirus*, with the former including human and avian metapneumoviruses, and the latter human and bovine respiratory syncytial virus (RSV), as well as murine pneumonia virus (MPV). Based on genetic and phylogenetic analysis, hMPV is divided into two groups, A and B, with each group divided in two subgroups, i.e., A1 and A2; B1 and B2. Subgroup A2 is again subdivided into A2a and A2b. Despite differences in genetic sequences, there is significant antibody cross-reactivity and neutralization capacity and therefore protection against various genotypes. All hMPV strains share similar genome and virion structure and several different hMPV genotypes cocirculate each epidemic season, with the predominant genotypes varying from season to season.

Virion Structure and Virus Proteins

In tissue culture, hMPV virions consist of enveloped pleomorphic, spherical or filamentous particles, ranging from 150 to 600 nm in size, with short protein spike projections of approximately 13–17 nm.

HMPV encodes 9 proteins, classified as either integral membrane proteins, embedded in the virus envelope, or internal proteins, which associate with the virus nucleocapsid beneath the virus envelope, as illustrated in [Fig. 1](#). The transmembrane proteins, which represent the virion spikes, are glycosylated and include the fusion protein F, glycoprotein G, and small hydrophobic protein SH. The F protein, which is well conserved among strains, mediates fusion of viral and cellular membranes during hMPV entry, it induces syncytium formation in infected cells, and determines the cellular host range. In addition, it is a major immunogenic protein. The functions of the G protein include cellular glycosaminoglycans binding (strain-dependent), and host immunity regulation. The SH protein, whose function is still unclear, also plays a role in modulating innate immune responses in airway epithelial cells (AECs) and dendritic cells (DCs).

There are five internal proteins, four of which are part of the nucleocapsid and polymerase complex: the nucleoprotein N, the phosphoprotein P, the transcription regulatory proteins M2-1 and M2-2, and the RNA-dependent RNA polymerase L. The viral genome interacts with N, P, and L to form the virus ribonucleoparticle (RNP). The matrix protein M surrounds the RNP underneath the virus envelope, and, together with the F and G proteins, plays an important role in virus assembly and budding. A summary of hMPV proteins and their function is presented in [Table 1](#). A further description of the various functions of hMPV proteins is presented in subsequent sections of this article.

Genome

The hMPV genome consists of about 13,000 nucleotides, with a size ranging from 13,280 to 13,378 nucleotides depending on the genotype, and it contains 8 genes, which encode 9 proteins, with the order of viral protein expression as the following: 3'-N-P-M-F-M2-1-M2-2-SH-G-L-5' ([Fig. 2](#)). Among those, M2-1 and M2-2 are both encoded by hMPV M2 gene. The M2-1 open reading

Fig. 1 hMPV virion structure. Schematic representation of name and location of hMPV proteins, either present in the envelope (F, G, SH) or underneath it (M), or associated with viral RNA (N, P, L, M2-1 and M2-2).

Table 1 hMPV proteins and function

Gene	Protein	Function
F	Fusion protein	Cell binding, membrane fusion, virus assembly
G	Attachment glycoprotein	Binding to cellular glycosaminoglycans, virus assembly, innate immune response inhibition
SH	Small hydrophobic protein	Innate immune response inhibition
N	Nucleoprotein	RNA genome encapsidation, virus intercellular spread
P	Phosphoprotein	Polymerase cofactor
M2	M2-1 protein	Essential for virus replication in vivo
	M2-2 protein	Viral RNA synthesis
L	polymerase protein	RNA-dependent RNA polymerase responsible for mRNA generation and genome replication
M	Matrix protein	Viral assembly and budding

frame (ORF) is presumed to start with the first AUG codon of M2, while the M2-2 ORF possibly initiates with the second or third AUG (s) of M2, overlapping the M2-1 ORF by about 50 to 40 nucleotides. HMPV RNA synthesis comprises two independent events: viral replication and viral gene transcription, which are carried out by three essential proteins: the nucleoprotein N, phosphoprotein P, and large protein L. In addition to these three proteins, studies using recombinant hMPV lacking M2-2 demonstrated that the M2-2 protein is also important for viral RNA synthesis. Whether hMPV M2-2 is a key regulatory factor involved in the switch of the viral RNA polymerase from viral gene transcription to viral genome replication, as with the RSV M2-2 protein, is still unknown. Although RSV M2-1 functions as a transcriptional elongation and antiterminator factor, and is essential for viral replication, hMPV M2-1 protein was found to be dispensable for virus viability or replication in tissue culture, although it was very important for replication in vivo, as its deletion resulted in a highly attenuated virus.

Life Cycle

The Entry of hMPV

The major cell target of hMPV infection is the airway epithelial cell, although it can infect other cell types, like macrophages and DCs, leading to abortive replication in those cells. hMPV F is sufficient for mediating virus entry, as hMPV lacking G or SH is still infectious, although hMPV B strain also uses the G protein to bind to glycosaminoglycans to improve viral fitness. HMPV F protein shares conserved functional domains with other pneumovirus F proteins, and requires cleavage from a precursor protein F0 into F1 and F2 as a prerequisite for fusion activity. In cell culture, it also requires the addition of exogenous proteases, different from the orthopneumovirus RSV. HMPV F attaches to cellular receptors, including integrins, via interaction with its Arg-Gly-Asp (RDG) sequence, and catalyzes virus membrane fusion with cellular membranes during virus entry. In addition to plasma membranes, hMPV particles have been shown to be internalized by clathrin-mediated endocytosis and then fuse with endosomal membranes. Engagement of RGD-binding integrins has been shown to be required for endosomal trafficking and full virus membrane fusion with intracellular membranes. Although low pH exposure was initially thought to be necessary for hMPV fusion, inhibition of

Fig. 2 HMPV genomic organization. Schematic representation of hMPV genome, illustrating gene order from the 3' to the 5' end and the M2-1 and M2-2 open reading frames both encoded by hMPV M2 gene.

endosomal acidification has only a modest effect on fusion for many hMPV viruses, and this event appears to be strain-specific. In addition to clathrin-mediated endocytosis, there is evidence that hMPV enters target cells via lipid rafts. When lipid raft inhibitors, such as cyclodextrin and nystatin were used, hMPV cell entry was inhibited. Virus internalization in immune cells, such as monocyte-derived DCs, seems to occur via macropinocytosis and also via clathrin-mediated endocytosis through the interaction with the C-type lectin receptor DC-SIGN.

Viral RNA Synthesis

Upon entry, viral nucleocapsids are released into the cell cytoplasm, followed by synthesis of viral components. It is generally believed that the viral synthesis of hMPV is similar to the better known pneumovirus RSV. The viral RNA-dependent RNA polymerase (RdRp) complex, formed by the L and P proteins, is presumed to bind the N-encapsidated genome at the leader region, then sequentially transcribes each gene by recognizing the start and stop signals flanking the viral genes, leading to synthesis of mRNAs, which are capped and polyadenylated. Protein translation occurs in the endoplasmic reticulum, with transport of proteins through the Golgi apparatus, for post-translational modifications, mainly glycosylation, to sites of virus assembly. Genome replication presumably starts when enough nucleoprotein is present to encapsidate newly synthesized antigenome and genome copies. The negative-sense genome is replicated into a positive-sense antigenome, which serves as a template for synthesis of many copies of the viral genome. In addition to P and L, the M2-1 and M2-2 protein are also important for viral RNA synthesis, as mentioned above. Recent structural studies on P protein revealed it to be a multifunctional hub which interacts with numerous components of the viral RNA-synthesis machinery, including the RNA-free N, the M2-1, the L polymerase, and the nucleocapsid, demonstrating its importance in viral RNA synthesis. Experimentally, colocalization of the virus -RNA, +RNA, mRNA, as well as, N and P proteins was found to occur in specific cytoplasmic structures called inclusion bodies (IBs), but not in others – such as stress granules, or processing bodies. This strongly suggests that IBs are the sites of active hMPV replication and gene transcription, similar to other negative sense RNA viruses, such as filoviruses and rhabdoviruses.

Viral Particle Assembly and Spread

From IBs, newly synthesized nucleocapsids are transported to assembly sites, likely via actin cytoskeleton, to be incorporated into nascent virions. Similar to human RSV (hRSV) and paramyxoviruses, the M protein plays a fundamental role in hMPV morphogenesis, however, its presence is not sufficient for the formation of virus-like particles, which requires the presence of the F, G and possibly N proteins. The fully assembled virions are then released into the extracellular environment from the apical surface of polarized infected cells. The process of budding and the release of hMPV has not yet been elucidated. Many enveloped viruses, including several paramyxoviruses, use the endosomal sorting complex required for transport (ESCRT) machinery for budding. However, recent studies have shown that hRSV does not utilize this pathway, similar to influenza A virus and alphaviruses, but employs a Rab11-dependent mechanism, which is part of the apical recycling endosomal pathway. Similarly, the ESCRT is not required for budding of the avian metapneumovirus C, which shares about 80% homology with hMPV, suggesting that it is unlikely to be involved in hMPV budding, as well. Viral RNA, and other viral components, can also be transferred to other cells via cell-to-cell syncytia formation or via formation of intercellular extensions, which have been shown to be covered by branching filaments that contain viral proteins and RNA, likely corresponding to filamentous hMPV virions. A summary of the virus life cycle is presented in Fig. 3.

Epidemiology and Clinical Features

hMPV was first discovered in the Netherlands in 2001. Through electron microscopy and real-time reverse transcriptase-polymerase chain reaction (RT-PCR), researchers identified this new viral agent in nasopharyngeal specimens collected from children with a respiratory illness. Since then, hMPV has been isolated in samples derived from a variety of age groups worldwide, with a higher prevalence in children younger than 5 years and adults older than 65 years of age. Although the disease burden for hMPV is lower compared to hRSV, the other important human virus member of the *Pneumoviridae* family, hMPV remains a cause of considerable morbidity and mortality, currently estimated at 33 million cases/year worldwide.

The virus is believed to have circulated for a very long time, as hMPV-neutralizing antibodies have been detected in stored serum samples from the 1990s and as far back as the 1950s. From seroconversion studies, we know that in the first few months of

Fig. 3 Schematic diagram of hMPV life cycle. Schematic representation of main steps of hMPV replicative cycle, from virus entry via endocytosis to RNA synthesis in specialized structures known as inclusion bodies.

life most children have maternally derived antibodies, and that primary infection occurs predominantly in the first two years of life, followed by common reinfections during childhood, with positive IgG and IgM detected during an acute respiratory illness.

In a similar fashion to RSV, and most viruses associated with respiratory illnesses, hMPV infections show a seasonal cycle which spans between November and May in temperate climates, with the peak of disease mostly occurring during the months of March and April. In recent surveillance studies conducted in the US from 2008 to 2014, the data confirmed previous observations that hMPV season occurs later than that of RSV, with the RSV season occurring first, followed by influenza, and then hMPV. In addition, the data demonstrated a biannual pattern of early and late seasons, which did not occur for RSV.

Different hMPV genotypes can circulate during the same epidemic year, and severe infection forms may be associated with different lineage viruses throughout the year. Some studies have suggested a correlation of specific genotypes with disease presentation, with hospitalization and diagnosis of pneumonia being more frequent in patients infected with genotype A, and wheezing with genotype B, however, there is no significant correlation with disease severity. The level of viral replication may also affect the clinical picture. Some studies have reported that, in the absence of a preexisting condition or immunosuppression, the disease severity and the duration of illness were associated with high hMPV viral load in the lower respiratory tract, although other studies showed conflicting results.

The incidence of hMPV infection is higher early in life, in fact it is two times more common among children before 2 years of age, compared to those between 2 and 5 years of age. Hospitalization is also most common during the first year of life. Among infants and very young children, prematurity and pre-existing heart and lung conditions have been identified as predisposing factors for a severe disease. The estimated prevalence of hMPV infection in hospitalized children is between 5% and 7%, with some studies reporting up to 10% of all pediatric hospitalizations for respiratory illnesses, with a rate of 1.2 hospitalizations per 1000 children <5 years old per year. In the outpatient population, the impact of hMPV on acute respiratory illnesses in the pediatric population becomes as high as 15% during the peak season.

hMPV infections in otherwise healthy young adults are usually mild and often go undetected, but it is known that reinfection occurs frequently during adult life, and the majority of adults have stable titers of neutralizing antibodies. Severity of disease increases again in the elderly, with higher morbidity and mortality rates, and hospitalization rates as high as 60%.

In addition to children and the elderly, patients with preexisting conditions such as pulmonary neoplasia, lymphoma, chronic obstructive pulmonary diseases or asthma are also at greater risk of developing pneumonia and respiratory failure. The relationship of hMPV to asthma is still under investigation, but current evidence seems to support both higher prevalence of hMPV in patients hospitalized due to acute asthma exacerbations, and a higher risk of developing asthma later in life for those patients who experienced severe disease from hMPV infection during childhood.

Coinfection with other respiratory viruses or bacteria may also occur. Dual infection with RSV has been more commonly reported, and there are conflicting results on whether virus co-infections lead to increased disease severity. Although less common than infection with influenza, superimposed bacterial pneumonia, whether a nosocomial infection or community-acquired, has been reported, which leads to increased mortality rate.

Infection with hMPV is acquired through proximity or contact with infected subjects, mostly via respiratory secretions (droplets) or fomites. After an incubation period of 4–6 days, patients usually develop symptoms associated with upper respiratory tract infection (URTI), which may include fever, sore throat, cough, and development of acute otitis media. Patients who progress with the development of a lower respiratory tract infection (LRTI) show tachypnea, dyspnea, wheezing and hypoxia. High fever, found frequently among hospitalized children, is less frequent in adults, especially compared to infection with RSV. In rare cases, seizures and encephalitis have also been reported in association with hMPV. The virus can be isolated in secretions for up to 14 days after the onset of symptoms, making person-to-person spread within families or communities common.

In the pediatric population, URTI symptoms last on average between 7 and 10 days, while LRTI requiring hospitalization have a longer duration. Bronchiolitis and interstitial pneumonia are usually confirmed by radiologic diagnosis. In systematic evaluations of the radiographic characteristics of acute respiratory illnesses associated with pediatric hMPV infection, peribronchial/perihilar opacities were the most commonly observed abnormality, occurring in 87% of children. Hyperinflation also occurred frequently (69%), with atelectasis (40%) and consolidation (18%) appearing less frequently. Subjects with different clinical diagnoses had different radiologic findings, e.g., children with pneumonia, were more likely to have consolidation and perihilar/peribronchial opacities, while children with asthma and bronchiolitis were more likely to have hyperinflation. When additional laboratory tests are performed, complete blood counts may show lymphopenia with or without neutrophilia, and abnormal chemistries, namely elevated transaminases on liver function tests.

In immunocompromised patients, and the elderly, the presentation of hMPV LRTI is usually pneumonia, which may be severe. Because of increased transmission and severe disease, the mortality rate associated with hMPV infection is higher in elderly patients confined within long-term care institutions.

Pathogenesis

Cellular Responses

The airway epithelium represents the primary infection site of respiratory viruses, including hMPV. After infection, epithelial cells, together with lung resident cells – such as alveolar macrophages, secrete a variety of innate immune molecules, including antiviral substances and proinflammatory and immunoregulatory cytokines and chemokines, which initiates specific hMPV immune responses, both innate and adaptive, that are protective, but also in part, pathogenetic. For example, the depletion of alveolar macrophages have been shown to decrease hMPV replication, lung inflammation and disease severity in a mouse model of infection. Similarly, type I interferon (IFN) secretion, which plays a role in controlling hMPV replication, is also a determinant of a disease, as mice lacking type I IFN receptor have less lung inflammation and airway dysfunction. Increased levels of cytokines and chemokines have been shown to correlate with clinical disease in animal models of infection. For example, the thymic stromal lymphopoietin (TSLP) has been recently found to induce pulmonary inflammation and enhance hMPV replication in mice, and to correlate with wheezing and disease severity in young children with the infection. IL-17 has been shown to suppress regulatory T cell recruitment, increase Th1 and Th2 cells and neutrophil lung influx, and be involved in airway dysfunction in the course of hMPV infection, suggesting that IL-17 skews the immune response in the lung toward an inflammatory profile.

Studies in mice have shown that neutrophils are the predominant cell type recruited to the airways early during hMPV infection. In this animal model, neutrophil depletion is associated with increased pulmonary inflammation and severe clinical disease, without changes in viral clearance, and with increased recruitment of lung $\gamma\delta$ T cells, suggesting that the latter cells contribute to hMPV-induced disease pathogenesis.

T cell responses are required for virus clearance in hMPV-infected mice, together with neutralizing antibody production, however, they also contribute to pathology. Depletion of CD4⁺ T cells reduces lung pathology and airway obstruction, without affecting viral replication, although it is associated with impaired generation of neutralizing antibodies. This impairment does not affect the protection against hMPV reinfection, suggesting that protection can be provided by an intact CD8⁺ T cell compartment. Cytotoxic CD8⁺ T lymphocytes have been shown to be capable of clearing hMPV in Rag^{-/-} mice, underlying their importance in hMPV protection, however, they have also been shown to contribute to pathogenesis.

Immunity to hMPV is incomplete, as reinfections can occur throughout the life. One mechanism utilized by hMPV to evade the adaptive immune response is the upregulation of programmed cell death-1 (PD-1) receptor on T cells and its ligand, PD-L1, in the lung, leading to functional impairment of hMPV-specific CD8⁺ T cells. Inhibition of PD-1 signaling, or lack of the receptor in a

Fig. 4 Schematic diagram of sites of antagonism of cellular signaling and IFN production/responses by hMPV proteins. Major cellular targets of hMPV proteins in the TLR4, RIG-I/MAVS and type I IFN signaling pathways. P indicates phosphorylation.

murine model of infection, result in a higher number of hMPV-specific CD8 + T cells, both during primary and secondary infections, suggesting that this pathway could play an important role in the ability of hMPV to reinfect the host.

Pattern Recognition Receptors (PRRs) and Antagonism of Immune Responses

Activation of the innate responses to infections is initiated by the recognition of specific pathogen-associated molecular patterns (PAMPs) derived from the invading pathogens, through a variety of host PRRs. Multiple PRR families, including RIG-I-like receptors (RLRs), Toll-like receptors (TLRs), and NOD-like receptors (NLRs), and their corresponding signaling adapters, have been shown to detect hMPV and initiate cellular responses to infection.

Retinoic acid-inducible gene I (RIG-I) and melanoma differentiation-associated protein 5 (MDA5) are the two major RLRs activated by hMPV infection and they share a common adapter, the mitochondrial antiviral-signaling protein (MAVS), for signaling. The RIG-I/MAVS pathway has been shown to be important for the cytokine/chemokine/IFN induction by hMPV in AECs, while MDA5 is essential to induce IFN secretion in human and mouse DCs, as well as, in an experimental mouse model of infection, where it plays a protective role against a severe disease. The role of MAVS in hMPV-induced inflammatory and antiviral mediator secretion has also been investigated in mice, and it was found to be necessary for the generation of protective innate immune responses, through immune mediator production and recruitment and maturation of immune cells, which in turn, modulate activation of T cell responses.

Several TLRs have also been shown to be important in hMPV-induced host responses. In human monocyte-derived DCs, TLR4 plays an important role in the induction of cytokines, chemokines and type I IFNs following hMPV infection. Its absence, in a mouse model of infection, is associated with significantly reduced lung inflammatory response, clinical disease severity, and airway dysfunction. TLR7 also plays a role in type I IFN production in response to hMPV infection, as TLR7-deficient plasmacytoid dendritic cells (pDCs) show reduced IFN- β secretion compared to wild type cells. Although the expression of TLR9 has been shown to be increased in a hMPV murine model of bacterial superinfection, its role in hMPV-induced host responses has not been revealed. MyD88 is a common TLR adapter, and its absence in DCs and in a mouse model of infection is associated with reduced proinflammatory mediators and type I IFN production, which results in amelioration of hMPV-induced pulmonary inflammation and clinical disease.

The elucidation of the role of NLRs in hMPV infection has only recently been initiated, therefore, limited information is available. HMPV has been shown to activate NLRP3 inflammasome in an SH protein-dependent manner both in cells and mice, playing a detrimental role during infection, as inflammasome inhibition ameliorates clinical disease and lung inflammation without affecting viral replication. Furthermore, children experiencing a more severe disease form have significantly higher cellular and secreted levels of the inflammasome-regulated NLRP3 and IL-1 β , respectively.

Like many other viruses, hMPV has developed strategies to subvert cellular signaling and antiviral responses. The P protein of hMPV-B strains, but not the one from A strains, suppresses RIG-I-dependent type I IFN production. The hMPV G protein has also been shown to suppress RIG-I-mediated immune responses in AECs by disrupting the RIG-I-MAVS interaction and to inhibit TLR4-mediated innate antiviral signaling in DCs. The SH protein of hMPV downregulates type I IFN signaling pathway by reducing the expression and phosphorylation of signal transducer and activator of transcription 1 (STAT1). SH also blocks type I IFN induction in pDCs by inhibiting the TLR7/MyD88/TRAF6 pathway, and suppresses the nuclear factor (NF)- κ B transcriptional activity in AECs. The M2-2 protein is also an important immune regulatory protein by targeting the common adapter molecules MAVS and MyD88. A summary of the viral protein antagonism of cellular signaling pathways is presented in [Fig. 4](#).

Diagnosis

As hMPV infection shares clinical signs and symptoms with a variety of other respiratory viruses, it is not possible to make a diagnosis based solely on the patient's clinical presentation, thus, laboratory testing is necessary to confirm the infection. HMPV can be detected by culture, nucleic acid amplification, antigen detection and serology, however, not all methods have clinical utility. Traditional virology methods, such as cell culture, are not very helpful with hMPV in clinical practice because isolation may take over 2 weeks, and the mild cytopathic effect caused by hMPV is not consistent among different genotypes. Furthermore, growing hMPV in cell culture requires exogenous trypsin and is only successful in a few specific cell lines.

Real time PCR, targeting usually either the N or the F protein gene, is the method of choice in most medical facilities for hMPV diagnosis – especially with the current availability of multiplex assays, which allow simultaneous detection of several respiratory viruses, and therefore, establishes the presence of virus coinfections.

Viral antigens can be detected in cells of respiratory secretions by immunofluorescence assay, but this method, despite being of value during seasonal epidemics, is less sensitive than RT-PCR. Enzyme-linked immunoassays (ELISA) can be used for serologic testing, however, as the majority of individuals test seropositive for hMPV after childhood, serology only yields useful information in cases of seroconversion, or when a four-fold increase in subsequent specimens is observed.

Imaging studies, such as chest radiography, and computed tomography without contrast, are clinically useful for the overall evaluation of the patient and clinical decision-making process, but hMPV cannot be differentiated from other respiratory infections associated with bronchiolitis or pneumonia on the basis of imaging alone.

Treatment

The treatment options available to those infected with hMPV are limited to supportive care with intravenous hydration and oxygen supplementation, if necessary. Similar to RSV infection, bronchodilators and corticosteroids have been used in patients with airway obstruction, with no clear benefits, therefore, they are generally not recommended for pediatric or adult patients.

Ribavirin and nonspecific polyclonal intravenous immunoglobulins (IVIG) have been used with mixed results in some specific cases and case series. Though preclinical studies of ribavirin and IVIG for the treatment of hMPV did show promising results, only sporadic case reports have shown positive outcomes when they were used in adults and children mostly immunocompromised due to cancer or solid-organ transplant. Because of conflicting conclusions, and the lack of randomized controlled trials, there is no recommendation regarding the therapeutic use of ribavirin, nor IVIG.

Several experimental products are under research and development for the treatment of hMPV, including specific monoclonal antibodies, fusion inhibitors, and small interfering RNAs. Among therapeutic immunoglobulins, monoclonal antibodies developed against hMPV are currently in the preclinical research pipeline, having shown efficacy *in vitro* and also *in vivo*, by reducing pulmonary viral load and severe disease in small animal models of infection. Additional therapeutic approaches under experimentation are fusion inhibitors and RNA interference, targeting primarily N and P proteins, which have been tested *in vitro* with a certain degree of effect.

Prevention

Currently, the prevention of hMPV infection is mostly achieved through epidemiological countermeasures. Standard droplet isolation infection control practices are recommended in clinical settings where infected patients are being treated, as well as, in long-term care facilities when cases of hMPV infection are suspected.

While a vaccine to prevent hMPV is not currently available, researchers are exploring different strategies to develop a safe and effective vaccine, including the generation of live-attenuated vaccines, vector and chimeric-based vaccines, as well as, subunit vaccines. Live-attenuated virus candidates in preclinical development include, cold-passaged temperature-sensitive strains and recombinant vaccine candidates generated by deletion (M2-2, G and/or SH proteins) or mutation (M2-1 or F proteins) of selected genes, which have shown good immunogenicity, and reduced viral replication in the lungs of various animal models of infection, with no enhanced disease – different from inactivated vaccines, both formalin and heat-inactivated, which increased disease pathogenicity. The recombinant virus lacking SH expression has been recently proved to be immunogenic in healthy adults, and it is now in the research pipeline as the parent virus for vaccine development.

Chimeric, virus-like particle and subunit vaccines have also been developed and tested primarily in rodent models of infection. In general, those vaccines that including the F protein were shown to be immunogenic and protective, however, in the case of the F subunit vaccine, the antibody levels seemed to rapidly wane in nonhuman primates.

Experimental monoclonal antibody preparations have also been studied for their prophylactic use to prevent severe disease. In rodent models, the use of these antibodies has shown promising results. In animals treated prior to hMPV challenge, viral load was low or undetectable in lung specimens and microscopic examination revealed reduced tissue damage compared to untreated or mock-treated animals.

This is an update of K.Y. Green, Noroviruses and Sapoviruses. In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-0-12374410-4.00555-0](https://doi.org/10.1016/B978-0-12374410-4.00555-0).

Introduction

Acute gastroenteritis (AGE) remains a major cause of morbidity and mortality in people in all age groups. Enteric caliciviruses, including human noroviruses and sapoviruses, are today recognized as important etiologic agents of this illness. However, before 1970, it was assumed that bacteria or parasites caused almost all acute infectious diarrhea. It was not until the introduction of electron microscopy (EM) and negative staining in the early 1970s that several viruses were discovered and found associated with acute diarrhea. In 1972, virus particles measuring 27 nm in diameter, were detected by immuno-electron microscopy in the feces of volunteers who had received filtered fecal suspensions from an outbreak of winter vomiting disease that had originated from a primary school and spread to the local community of Norwalk in the US. The particle was therefore first named 'Norwalk agent'; decades later, it was named norovirus and has a 'star of David' appearance under EM (**Fig. 1**). It has now been established as a causative agent for one-fifth of all acute gastroenteritis, with approximately 200,000 deaths annually worldwide.

In 1976, Madeley and Cosgrove and Flewett and Davies, reported morphologically 'typical human caliciviruses' in the feces of children with acute gastroenteritis. In the years that followed, these viruses were detected by several investigators and were named 'typical human caliciviruses' or 'Sapporo-like viruses' after an outbreak in 1982 in Sapporo, Japan. Today, these viruses are known as sapovirus.

Although human norovirus and sapovirus were first detected nearly five decades ago, several questions related to their pathogenesis and host–virus interactions still remain unanswered, partly due to the lack of a small-animal model and the inability to cultivate these viruses in vitro. However, most recently, human intestinal enteroids (HIEs) originating from stem cells in the small intestine have been established and are being used successfully to propagate human noroviruses. This recent major breakthrough has increased our knowledge of norovirus biology significantly. It is anticipated that the recent successful cultivation of sapovirus in HIEs will also lead to a similar advancement of understanding.

Norovirus

Viral Classification

Norovirus is a genus in the family *Caliciviridae*, which also includes the genera Bavovirus, Lagovirus, Minovirus, Nacovirus, Nebovirus, Recovirus, Salovirus, Sapovirus, Valovirus, and Vesivirus (**Table 1**). The norovirus genus contains a diverse group of viruses that infect several mammalian species including humans, dogs, cats, pigs, mice, and cattle.

The classification within the norovirus genus has changed significantly through the years and was recently updated.

Noroviruses are classified into 10 capsid genogroups (GI to GX) based on amino acid sequence diversity of the complete major capsid gene (VP1). Strains that infect humans belong to GI, GII, and GIV genogroups, with GI and GII causing the vast majority of human disease. Similarly, partial RNA dependent RNA polymerase (RdRp) nucleotide diversity is used to classify norovirus into eight P-groups (GI.P, GII.P, GIII.P, GIV.P, GV.P, GVI.P, GVII.P, and GX.P).

These genogroups are further divided into capsid (VP1) or RdRp genotypes. This dual genotyping system can account for that recombination is a major factor in norovirus diversity, with the major recombination site present in the junction between the RdRp and VP1 genes (open reading frame [ORF]1–ORF2 junction).

Today, VP1 genogroup GI has been divided into nine capsid genotypes (GI.1–GI.9) and GII into 27 capsid genotypes (GII.1–GII.27). The GI.P and GII.P RdRp genogroups are divided into 14 and 37 P-genotypes, respectively (GI.P1–GI.P14 and GII.P1–GII.P8, GII.P11–GII.P13, GII.P15–GII.P18, GII.P20–GII.P41). The division into VP1 capsid genotypes is based on the amino acid diversity of the complete VP1 gene, whereas the P-genotype is currently based on the nucleotide difference of 762 nucleotides at the 3' end of ORF1.

The predominant human genotype GII.4 is further classified into variants based on phylogenetic clustering after becoming epidemic in at least two geographical locations.

Genome

Human norovirus is a single-stranded positive-sense RNA virus [ssRNA(+)]. The genome is ~7.5 kb long and organized in three ORFs. The genome is covalently linked to a virus-encoded protein called VPg at the 5' end, and is polyadenylated at the 3' end

Table 1 Calicivirus classification detailing genus and type species

<i>Genus</i>	<i>Type Species</i>
Norovirus	Norwalk virus (NV)
Sapovirus	Sapporo virus (SV)
Lagovirus	Rabbit hemorrhagic disease virus (RHDV) European brown hare syndrome virus (EBHSV)
Vesivirus	Vesicular exanthema of swine virus (VESV) Feline calicivirus (FCV)
Nebovirus	Newbury – 1 virus (NBV)
Recovirus	Tulane virus
Valovirus	St Valerian calicivirus
Bavovirus	Chicken calicivirus
Nacovirus	Turkey calicivirus
Salovirus	Atlantic salmon calicivirus
Minovirus	Fathead minnow calicivirus

Adapted from Desselberger, U., 2019. Caliciviridae other than noroviruses. *Viruses* 11, 286. Jan Vinjé, J., Estes, M.K., Esteves, P., *et al.*, 2019. ICTV virus taxonomy profile: Caliciviridae. *Journal of General Virology* 100, 1469–1470.

(Fig. 2(A)). The untranslated regions (UTRs) at either end of norovirus contain conserved RNA secondary structures important for viral replication, translation and pathogenesis.

ORF1 encodes a large polypeptide that is cleaved by the virally encoded cysteine proteinase into six mature non-structural proteins (Fig. 2(A)).

ORF2 encodes the major structural protein, VP1, which in turn is organized into internal shell (S) domains and protruded domains (P). The S domain is the most conserved part of the VP1 gene. The P domain can be further divided into the P1 domain and the hypervariable P2 domain, which encodes epitopes that are targets for neutralizing antibodies as well as sites involved in binding to attachment factors/receptor.

ORF3 encodes a minor structural protein called VP2, which has a putative role in assisting capsid assembly and genome encapsidation.

Virion Structure

Early experiments to understand norovirus virion structure using electron cryo-microscopy and image processing techniques involving recombinant Norwalk-like virus (rNV) particles have shown that norovirus exhibits $T = 3$ icosahedral symmetry,

Fig. 2 Norovirus and sapovirus genome organization. (A) The norovirus genome consists of three open readings frames. ORF1 (in grey) encodes the nonstructural proteins, with ORF2 (in green) and ORF3 (in blue) encoding the structural proteins VP1, the major capsid protein, and VP2, a minor structural protein, respectively. The non-structural polyprotein of ORF1 is processed by the cysteine protease (Pro), into six mature proteins: p48, an N-terminal protein proposed to be involved in replication complex formation; NTPase, a nucleoside triphosphatase; p22, a protein of unknown function but proposed to be involved in replication complex formation; VPg, covalently attached to the 5' end of the viral genome and involved in translation and replication; Protease, the cysteine proteinase, and RdRp, which is the viral RNA-dependent RNA polymerase. The major capsid protein is further divided into the shell and protruding domains (P), with the P domain subsequently divided into two different subdomains, P1 and P2. The approximate size of proteins expressed as number of amino acid (aa) are from the GII.4 MD-145 strain (AY032605). (B) Sapovirus genome consists of two open reading frames, ORF1 (non-structural proteins and VP1, in grey and green, respectively) and ORF2 (VP2, in blue). A subgenomic RNA is also produced during replication. A viral protein (VPg) is linked to the 5' end and a poly-A tail to the 3' end of both the genomic and subgenomic RNA. The approximate size of proteins expressed as number of amino acid (aa) are from the GI.1 Manchester strain (X86560).

wherein 180 capsid protein molecules form 90 dimers. X-ray crystallography studies have revealed that the capsid protein structure has S domain and a P domain, which are linked by a flexible hinge. The NH₂ terminal part of the capsid protein (up to 225 aa) is involved in the formation of the icosahedral shell, while the P domain is formed by two subdomains, i.e., P1 (aa 226–278 and aa 406–520) and P2 (aa 279–405).

Life Cycle

Until recently, there were no robust cell culture systems supporting human norovirus propagation, which has hampered the study and characterization of the viral life cycle. Hence, most information on the norovirus life cycle is obtained from surrogate virus systems such as murine norovirus and feline calicivirus, or the use of gnotobiotic pigs that can be infected with human norovirus. Different human norovirus replicon systems have also been used. These models have provided some insight into the life cycle of human noroviruses, but all with specific limitations. Murine norovirus, for example, is a common model for molecular studies due to the availability of cell culture and reverse genetics systems, but differs from human norovirus in terms of host interaction and pathogenesis. The recent development of human intestinal enteroids (HIEs) able to propagate human norovirus *in vivo* have already provided new insights into the human norovirus life cycle, and will be an essential tool for future studies.

Enterocytes in the small intestine are likely the primary sites of norovirus infection. Biopsies from immunocompromised patients with chronic norovirus infections have shown the presence of viral antigens in small-intestine enterocytes. Small-intestine enterocytes were also norovirus antigen-positive in a gnotobiotic pig model of human norovirus infection, and human noroviruses can be propagated in enterocytes present in *in vitro* culture systems of HIEs. Moreover, B-cells can be infected with human norovirus *in vitro*, although evidence of B cell infection *in vivo* is lacking. Patients with severe combined immunodeficiency (SCID) who lack B cells can be infected with norovirus, albeit with a slightly lower viral load. Thus, B cells are not essential for infection and replication but may be important for norovirus pathogenesis, although further studies are needed to determine their exact role.

Much is still unknown of the different steps of the live cycle of norovirus infecting a cell. However, an essential feature is that attachment factors for most human norovirus are cell-associated host glycans such as HBGAs (histo blood group antigens) present in epithelial surfaces of the small intestine, which can facilitate entry into the cell. For example, non-secretors, lacking the expression of α 1,2-linked fucosylated HBGAs in the small intestine are not infected with the predominant GII.4 genotype. Furthermore, GII.4 strains of human norovirus only infect HIEs derived from secretors but not those from non-secretor individuals. The soluble form of HBGAs and bile salts also increase virus infectivity. The subsequent receptor engagement remains unknown for norovirus. Several models have been proposed, such as binding to glycosphingolipids on the cell surface, followed by the invagination and release of norovirus-containing vesicles by dynamin II-mediated scission of the invagination, and viral genome release into the cytosol. The VPg-linked RNA genome of norovirus will subsequently act as an mRNA, where the VPg

protein is important for mediating translation and replication. Translation of the ORF1 polyprotein is followed by co-translational and post-translational processing by a viral protease, resulting in replication complex formation. Translation of the viral proteins VP1 and VP2 occurs mainly from the subgenomic RNA (sgRNA), likely to produce higher levels of the major capsid protein for virus assembly, as the sgRNA is present at higher levels and each icosahedral capsid contains 180 copies of VP1.

The processes behind norovirus assembly, encapsidation, and exit are largely unknown. The ability of VP1 to self-assemble into virus-like particles (VLPs) that are morphologically and antigenically highly similar to native virions suggests that capsid assembly during virus replication may occur without the involvement of cellular proteins.

Non-enveloped viruses, including norovirus, were usually thought to exit infected cells through cellular lysis. Recent findings, however, have shown that cell destruction is not always necessary for norovirus exit. Stools from infected people show norovirus residing in vesicles of exosomal or plasma membrane origin, which indicates that at least some norovirus are shed non-lytically inside exosomes.

Epidemiology

Norovirus causes sporadic and epidemic gastroenteritis in both children and adults and has been described from a variety of geographic regions and settings. The estimated global prevalence of norovirus is approximately 20% of all cases of AGE. Norovirus is also common in asymptomatic infections, with a globally estimated prevalence of 7%. All ages are affected, but the incidence is the highest in children aged <5 years. Norovirus is estimated to cause approximately 200,000 deaths annually worldwide, with 70,000 or more among children in developing countries. In children, norovirus is typically second only to rotavirus in causing acute gastroenteritis, and in several countries with national rotavirus immunization, it has become the most common etiology in children with AGE.

Norovirus is mainly transmitted through the fecal-oral route. Besides sporadic cases, norovirus is also the most common agent in outbreaks of gastroenteritis due to its high stability in the environment and ease of spread through contaminated water and food (Table 2). Waterborne norovirus outbreaks have been linked to potable water, wells, recreational water use such as swimming, and fountains. Norovirus is further estimated to be responsible for almost 50% of foodborne outbreaks globally. Fruits, vegetables, berries, shellfish, cereals, spices, and oysters are common in foodborne norovirus outbreaks, as they are consumed raw and subject to contamination from water sources. Contamination of food can also occur during its preparation.

Norovirus outbreaks occur frequently in settings with close human contact, such as schools, nursing homes, retirement communities, cruises, hotels, hospitals, or day care centers. The spread during an outbreak is predominantly via direct contact, exposure to aerosols or fomites. Many factors contribute to norovirus transmission and its ability to cause outbreaks. Norovirus is an extremely stable particle in the environment, and is highly resistant to disinfectants such as alcohols and to freezing and high temperatures. Furthermore, a low dose, i.e., 10–100 viral particles, is required for symptomatic infection, and norovirus can be shed in the stool at up to $1-10^{10}$ genome equivalents per g feces, and up to 10^6 genome equivalents per ml of vomit. Prolonged asymptomatic shedding further increase the risk of secondary spread (Table 2).

Seasonality

As the term ‘winter vomiting disease’ implies, norovirus infections exhibit a clear winter seasonality in many countries. This winter seasonality, however, is predominant in temperate regions, with peaks in December–February in the Northern Hemisphere or June–August in the Southern Hemisphere. In many tropical regions, such as Sub-Saharan Africa or South America, less data is available. Studies from several tropical countries have reported no or less clear patterns of seasonality. In some tropical countries

Table 2 Characteristics of norovirus facilitating transmission in different outbreak settings and in person-to-person transmission

Characteristics	Observations	Consequence
Stability	High survival in the environment. Resilient to freezing, heating and disinfectants such as alcohols	Difficult to eliminate in water and surfaces, leading to infections from e.g., oysters, recreational water, food irrigated with sewage, and fomites. Increased risk of infections in closed settings such as hospitals
Long-term/Asymptomatic shedding	Patients can shed norovirus up to three weeks after resolution of symptoms. Immunocompromised patients shed the virus even longer	Increased risk of secondary spread, can be particularly problematic concerning food handlers.
Viral diversity	Multiple genetic and antigenic strains exist, using different attachment factors in humans	Re-infections can occur more easily with different strains. Diagnostic and detection methods may not be sensitive for all strains
Low infectious dose High viral load in feces and vomitus	Only ~10–100 virus particles are needed for symptomatic infection	Increases risk of person-to-person transmission, aerosols, secondary spread, food, water and surface contamination
Short-term immunity	Symptomatic re-infection with homotypic strains can occur	Symptomatic re-infections occur. Adults are not protected although infected as children. May hinder development of effective vaccines with long-term protection

Note: Modified from Nordgren, J., 2009. Norovirus epidemiology: Prevalence, transmission, and determinants of disease susceptibility. Linköping: Linköping University Electronic Press. Patel, M.M., Hall, A.J., Vinjé, J., Parashar, U.D., 2009. Noroviruses: A comprehensive review. Journal of Clinical Virology 44, 1–8.

such as Nicaragua, norovirus peaks during the rainy season, and its prevalence has been associated with average rainfall in other countries, whereas some studies have found an association with rainfall only for norovirus outbreaks, and not for sporadic cases. The impact of rainfall on norovirus infections is not understood, but may be linked with environmental spread of the virus.

Molecular epidemiology

Genotype GII.4 is the predominant genotype worldwide for both sporadic infections and outbreaks of norovirus. A global review of norovirus in children (aged <18 years) found GII.4 accounting for 70% of the capsid genotypes and 60% of the polymerase genotypes, followed by the capsid genotype GII.3 (16%). A further systematic review of norovirus in low-income countries found that GII.4 was the predominant genotype in all settings (47%), followed by GII.3 and GII.6. The most prevalent GI strain was GI.3. In some geographic settings, other capsid genotypes such as GII.17 and GII.2, can become temporarily predominant. Nevertheless, >50% of norovirus infections yearly are caused by norovirus GII.4, with pandemics occurring every ~2–7 years. The first known human norovirus pandemic occurred in 1995–1997, with subsequent pandemics in 2002, 2004, 2006, 2009, and 2012. The reason GII.4 is the pandemic-causing genotype is not fully understood but could be related to higher biological fitness, seen as higher levels of viral shedding in infected patients, more diverse attachment receptor specificity and fast mutation frequency leading to antigenic drift and putative change of HBGA attachment factors, both leading to escape of previous herd immunity. The predominant genotype GII.4 has been linked to more severe symptoms and is less common in asymptomatic infections. Some studies have indicated that genotype GII.4 is relatively less common in food and waterborne outbreaks compared to other non-GII.4 or non-GI strains, which might be associated with higher resistance of some genotypes to environmental factors.

Population genetics and norovirus epidemiology

HBGAs, specifically the secretor, Lewis and ABO families, are strongly associated with susceptibility to norovirus in a genotype-dependent manner. Secretor status, mediating the presence of α 1,2 fucose-linked blood group antigens in epithelial surfaces of the small intestine, has been strongly linked to susceptibility to a wide array of norovirus genotypes. As expression of these HBGA glycans are linked to ethnicity and differ widely between populations, this likely has an effect on norovirus epidemiology. Many common norovirus genotypes such as the predominant GII.4, the recently emerging GII.17 and the common GII.6 genotype have all shown strong secretor specificity. Other genotypes, whose clinical importance in many cases is unknown, infect both secretors and non-secretors. As no genotype infects non-secretors exclusively, it is likely that populations with a high prevalence of secretors are more infected with GII.4 as well as other secretor specific or non-specific genotypes, which might lead to differences in disease burden, particularly as genotype GII.4 is associated with more severe symptoms.

Clinical Features

Norovirus cause vomiting and diarrhea, both of which may happen together or independently. The incubation period is short, usually 1–2 days, with symptoms lasting 2–3 days. Besides vomiting and diarrhea, abdominal pain, fever, headache, chills, myalgia, and malaise can also occur. Other unusual symptoms include encephalopathy and convulsions. Convulsions among norovirus-infected children are reported more often than for rotavirus infections. Norovirus disease is more severe among the elderly and people with accompanying medical conditions. Besides old age, very young children are also vulnerable. A study from Japan reported that the duration of illness among children aged <2 years was twice that in children aged 2–4 years. Additionally, hematopoietic stem cell transplant (HSCT) recipients and other immunocompromised individuals can have persistent norovirus infection with a duration of months or even years.

Pathogenesis

Until very recently, the lack of a cell culture system and an efficient animal model restricted our knowledge of norovirus pathogenesis. Our limited understanding has been obtained from histological or biochemical studies among human volunteers and data from porcine, bovine, and murine models. Histological examination of the small intestine of norovirus-infected human volunteers showed villi broadening and blunting, microvilli shortening, increased cytoplasmic vacuolization, and intercellular oedema. Like rotavirus infection, norovirus infection results in delayed gastric emptying.

Besides epithelial cells, human norovirus capsid protein has also been detected in macrophages, T cells and dendritic cells (DCs) of norovirus-infected immunocompromised patients. Recently, in vitro studies have reported human norovirus propagation in differentiated human intestinal organoid/enteroid cultures, and in a few established human B cell lines.

Mild inflammation of the lamina propria has also been reported in volunteer studies and animals. A large amount of understanding on norovirus pathogenesis comes from a murine infection model. Murine strains that cause both acute (MNV-1 and CW3) and persistent (CR6 and MNV-3) infection have been used to better understand norovirus pathogenesis. During the initial phase of MNV-1 infection in mice, the macrophages, DCs, B cells and T cells in the gut-associated lymphoid tissues become infected. It is suggested that murine noroviruses that cause acute infection involve M cells to overcome the epithelial barrier and cause initial infection. On the other hand, persistent murine norovirus strain CR6, which can be continuously shed in feces has been reported to infect tuft cells. Besides immune cells in the gut, MNV-1 infection also leads to extra-intestinal spread in immunocompetent mice with MNV-1 virus reportedly detected in spleen, liver, lungs, and lymph nodes. Furthermore, STAT1 (signal transducer and activator of transcription 1) not only limits MNV-1 virus replication in the intestines but also limits its spread to the peripheral tissues; however, MNV-1 infection in STAT1-deficient mice resulted in weight loss, gastric bloating, and

diarrhea. Differences in disease severity between MNV-1 and MNV-3 norovirus strains have been reported in wild-type mice, wherein MNV-1 results in modest to severe intestinal pathology, whereas MNV-3 infection is attenuated. Another interesting aspect was that no correlation between viral titres and disease severity was observed. Wild-type mice infected with MNV-1 showed intestinal pathology, while high viral load with no intestinal pathology was observed in MNV-3-infected wild-type mice. Although there are some similarities between human and murine noroviruses, such as involvement of carbohydrate attachment factors, and potential for continued viral shedding, there are certain differences as well, most notably is the inability of murine norovirus to produce severe diarrhea in mice.

Recent studies have been addressing the role of the host microbiota in norovirus infections. It has been reported that human norovirus interacts with both commensal and pathogenic bacteria via norovirus capsid and HGBA-like carbohydrates expressed on bacterial surfaces. Antibiotic-administered mice prevented persistent murine norovirus infection. However, it should be noted that infection of HIEs with human norovirus clinical isolates does not require bacteria, warranting further research on the importance of commensal bacteria in human norovirus disease.

It has also been suggested that norovirus might serve as a trigger for intestinal bowel syndrome or intestinal bowel disease. Norovirus infection increases intraepithelial cytotoxic T cells in the duodenum for up to 6 days after the onset of symptoms. Additionally, apoptosis of norovirus-infected epithelial cells has also been suggested.

Immunity

Protection from norovirus can be divided into genetic and immunological components. Briefly, the genetic factors for norovirus susceptibility are associated with expression of HBGAs in the small intestine. Secretor status is defined by the presence of a functional fucosyltransferase 2 (FUT2) enzyme which determines the presence of α 1,2 fucose linked HBGAs (A, B, H-type 1, and Lewis b). Lack of a functional FUT2 enzyme (yielding the so-called secretor-negative phenotype) is a strong restriction factor for several norovirus genotypes, including the predominant genotype GII.4. The overall prevalence of the non-secretor phenotype is approximately 20%, but large differences exist between populations.

Immunologically, humoral responses have an important role in the protection against norovirus infection. Higher serum levels of antibodies blocking norovirus VLP binding to HBGAs correlate with a lower risk of developing illness to some norovirus genotypes. The potential mechanism of action is blocking of the HBGA binding site of the virus capsid hindering the attachment to HBGAs on the cell surfaces of the small intestine. Higher levels of norovirus-specific memory B cells also correlate with lower risks of developing illness. This in combination with that immunodeficient persons lacking B-cells can develop chronic norovirus infections, suggest B cells to be important for preventing norovirus infection. Cross-reactive antibodies can be developed after infection, and immune response following infection of one genotype can provide protection against other genotypes. However, norovirus infections do not elicit long-lasting immunity, and a person can develop symptoms upon reinfection even with the same norovirus strain. The estimates of the degree and duration of homotypic and/or heterotypic protection after infection varies widely.

Diagnosis

Since the initial detection of norovirus using electron microscopy in the early 1970s, various diagnostic approaches have been used to detect noroviruses in clinical and environmental samples. Currently, both antigen and molecular (for detecting viral genome) tests are widely used.

(1) Antigen tests

Enzyme immunoassays

Enzyme immunoassays have been developed for norovirus GI and GII antigens in feces, but these assays have varying sensitivity (32%–92%) and specificity (65%–100%). Although most kits include cross-reactive monoclonal and polyclonal antibodies, variability in norovirus load in clinical specimens, the circulation of antigenically distinct genotypes and variability within the genotype due to antigenic drift affect their performance. However, their biggest advantage is the high throughput and feasibility for use in laboratories with minimum infrastructure.

Besides conventional enzyme immunoassays, Immunochromatographic (ICG) lateral flow assays can be used for rapid detection as they do not require specialized laboratory equipment or highly trained personnel. However, their low sensitivities, warrant further screening of the negative samples.

(2) Molecular tests

Reverse transcription-PCR (RT-PCR)-based assays are today considered the gold standard for detecting norovirus and have been continuously updated over time to ensure high specificity and sensitivity.

Conventional RT-PCR

One of the first RT-PCR assays used primers to the first detected norovirus strain, the Norwalk virus. Subsequent generations of RT-PCR assays used primers from a more conserved region (the viral polymerase gene). Although having higher performance than that of enzyme immunoassays; hybridization or sequencing was required to ensure high specificity and sensitivity. Another

shortcoming of the conventional RT-PCR over real-time RT-PCR is the processing required for visualizing the amplicon after genome amplification.

Real-time RT-PCR and multiplex molecular assays

Real-time RT-PCR assay today is the most common method for norovirus detection. It is usually applied in a multiplex fashion to distinguish GI and GII genogroup noroviruses. Most real-time PCR assays use primers and probes targeting the most conserved part of the norovirus genome, the ORF1-ORF2 junction.

Recently, the use of large multiplex molecular assays (Biofire FilmArray Gastrointestinal Panel, Luminex xTag Gastrointestinal Pathogen Panel, and Taqman Array Card) for simultaneous detection of known gastrointestinal pathogens, including viruses, has increased. This reduces the turnaround time for accurate results and aids in identifying infections and/or co-infections that remained undiagnosed by routine test methods for single pathogens.

Single-unit tests

Besides multiplex assays, there also exist single-unit, easy-to-use norovirus automated molecular detection tests that require very little time, and staff training, and one such assay is the Xpert Norovirus assay (Cepheid, Sunnyvale, CA, USA).

Treatment

In immunocompetent individuals, norovirus gastroenteritis is self-limiting, and the treatment of norovirus gastroenteritis is generally supportive. Administering oral rehydration solutions (ORS), or intravenous rehydration, is the primary treatment strategy for correcting the altered electrolyte and fluid imbalance. Antiemetics, such as ondansetron can also be given to reduce vomiting and facilitate oral rehydration therapies. Loperamide, an anti-motility drug, is often used by travellers; however, its use in children is not recommended in all countries.

Therapeutics for persistent norovirus infection is of clinical importance and studies involving antiviral therapy to norovirus are limited. Nitazoxanide, a broad-spectra antiparasitic and antiviral agent, shortened the duration of norovirus illness, and resolved diarrhea in a norovirus-infected patient with refractory acute myelogenous leukemia and HSCT. Similarly, enteric administration of human immunoglobulin resolved chronic diarrhea in a transplant patient. Besides oral immunoglobulins and nitazoxanide, the anti-viral drug ribavirin has been linked to viral clearance in common variable immunodeficiency (CVID) patients.

Prevention

Norovirus spreads from person-to-person, contaminated food, water and other environmental contaminants. Thus, epidemic outbreaks as well as food and waterborne outbreaks are common, with norovirus being responsible for ~50% of foodborne AGE outbreaks. Various fruits and ready-to-eat vegetables that come into contact with contaminated water are often the source of norovirus-related food borne outbreaks. To date, there is no consensus regarding what viral load should be considered as a cut-off for contamination. However, a recent study using HIE model reported that a ct (threshold cycle) cutoff of 30 in a fecal sample could be considered as infectious. One of the ways of preventing norovirus infection is to ensure that water used for irrigation, washing vegetables or culturing shell fish is not contaminated with norovirus. Another major issue to be considered is that the water used for irrigation be pre-treated and not contaminated with fecal wastewater.

Besides food itself, the norovirus can also be transmitted via restaurant personnel infected with norovirus, who are often the index source of foodborne norovirus outbreaks in restaurants or cruises. Hence, appropriate disinfection measures are needed to prevent this contagious disease. Good hand hygiene remains an important measure for controlling norovirus spread. Cleaning with soap and running water is better for removing norovirus than alcohol-based hand disinfection. Until very recently, the lack of a cell culture system for propagating human norovirus hindered assessment of norovirus inactivation systems. A recent study using HIEs as a model to examine the effect of chlorine and alcohols (ethanol and isopropanol) on inactivating human norovirus infectivity. The authors reported that, irrespective of alcohol treatment duration/concentration, complete norovirus inactivation could not be achieved. On the other hand, chlorine treatment resulted in a complete norovirus inactivation.

In norovirus outbreaks in hotels, restaurants or cruise ships, besides isolating infected individuals and maintaining personal hygiene, the disinfection of contaminated surfaces is equally important. These include tables, chairs, commodes, doorknobs, bathroom, floors, and carpets. Hypochlorite at a minimum concentration of 1000 ppm and quaternary ammonium compounds are preferred for decontaminating surfaces and objects although the latter are less effective. In health care settings, limiting norovirus spread at the earliest instance is of utmost importance. Besides following the above routine disinfection procedures, additional measures such as discarding all unused disposable items present in the patient's room should be considered.

Vaccination

There is no licensed norovirus vaccine available till date; however, there are vaccine candidates at various stages of clinical development. Most of these are VLP-based vaccines administered through an oral, intranasal, or intramuscular route. Recently, a safety and immunogenicity study of a bivalent (GI.1/GII.4) VLP-based vaccine (administered intramuscularly) showed that it was well tolerated and elicited pan-immunoglobulin and HBGA-blocking antibodies. Furthermore, a single-site, randomized, double-blind, placebo-controlled clinical trial of an oral non-replicating adenovirus-based vaccine expressing VP1 gene of the GI.1

norovirus strain with a double-stranded RNA (dsRNA) adjuvant showed that it was well tolerated and generated both systemic and mucosal immune responses.

Sapovirus

Classification

The family *Caliciviridae* consists of 11 genera including sapovirus (Table 1). Human sapoviruses are highly heterogeneous, and genetic classification is usually based on phylogenetic analyses of the sequence of the major capsid gene VP1, the most diverse region of the genome. Today, sapoviruses are divided into 15 genogroups, of which viruses within genogroups GI, GII, GIV and GV infect humans. Viruses in the other genogroups have been detected in swine (GIII and GV–GXI), sea lions (GV), mink (GXII), dogs (GXIII), bats (GXIV, GXVI–GXIX), and rats (GXV). These genogroups are further divided into genotypes, but a standardized genotyping method is still lacking, although this would be important in order to facilitate worldwide comparison of the data. The International Calicivirus Scientific Committee in 2010 proposed that new sapovirus genotypes should only be assigned based on the complete capsid sequence.

Virion Structure

Human sapoviruses are about 30–38 nm in diameter and have an icosahedral structure, with characteristic cup-shaped depressions on the surface, and are morphologically distinguishable from other gastroenteritis viruses (e.g., rotavirus, astrovirus or adenovirus) by the ‘star of David’ appearance. The surface structure is formed from 180 copies of the VP1, arranged in a $T = 3$ icosahedral symmetry. Each VP1 subunits contains two principal domains: the S and P domains, which are connected via a flexible hinge region.

The major component of the complete virus, VP1, is a ~60-kDa protein, while the VP2 protein has not been identified in the virion but is predicted to be a strong basic protein in the interior of norovirus particles. VP1 expression results in the spontaneous assembly of VLPs.

Genome

The human sapovirus genome is a 7.4–7.5 kb ssRNA(+). The genome contains two ORFs (Fig. 2(B)). A sgRNA consisting of VP1 and VP2 genes is also produced during replication. The viral protein VPg is covalently attached to the 5′ end of genomic RNA and sgRNA, and the 3′ end is polyadenylated. ORF1 encodes a polyprotein that is cleaved post-translationally into non-structural proteins (NS1, NS2, NS3, NS4, NS5, and NS6–NS7) and a major capsid protein VP1, whereas ORF2 encodes the minor capsid protein VP2. A third ORF (ORF3) has been predicted in several human and bat sapovirus strains; however, its function is unknown.

Life Cycle

There is yet no cell culture model for the human sapovirus, which has limited our knowledge of its replication cycle. Most of replication cycle studies of the *Caliciviridae* family arise from feline and murine norovirus studies and from porcine sapovirus in porcine cell lines. It is thought that sapovirus has a similar replication cycle to norovirus, with receptor binding, endocytosis, uncoating and release of genomic RNA into the cytoplasm. The endocytosis of porcine sapovirus has been shown to be clathrin- and cholesterol-mediated. Bile acids likely support porcine sapovirus replication via escape from the late endosome into the cytoplasm to initiate virus replication, as in the absence of bile acid, the virus remains in the late endosomes/lysosomes and is destined to be degraded. Recently, it was shown that porcine sapovirus-infection induced an early activation of the PI3K-AKT (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha-AKT) and MEK-ERK (extracellular signal-regulated kinase) pathways that facilitated early to late endosome trafficking as well as the acidification and release of virus from the late endosome. The dsRNA genome is synthesized from the genomic ssRNA(+), and transcribed/replicated, thereby providing viral mRNAs/new ssRNA(+) genomes. Calicivirus genomes do not have a 5′ cap structure; instead, a small virus-encoded protein (VPg) is covalently linked to the 5′ end of the genome. Similar, the porcine sapovirus genome is covalently linked to VPg, and this linkage is required for the translation and infectivity of viral RNA. The VPg protein is bound directly to the 4F subunit of the eukaryotic translation initiation factor (eIF4F) complex in infected cells, which was required for initiating viral translation and infectivity. Lytic or non-lytic mechanisms encapsidate the genomic RNA during virus assembly and release. Moreover, the cyclooxygenase/prostaglandin E2 (COX-PGE2) pathway is induced during porcine sapovirus replication, a mechanism proposed to be used by the virus for efficient viral growth and which could provide a potential future target for the control of sapovirus replication.

Epidemiology

Sapovirus has been detected all over the world, both in outbreaks and sporadic cases and is a public health concern. The virus infects and causes disease in people of all ages but is most common in young children and the elderly. Similar to norovirus, sapovirus shows winter predominance in many countries. A recent 1-year study of out-hospitalized patients in Spain found that

sapovirus was the second major gastroenteritis pathogen, with a prevalence of 15%, and was most prevalent in infants, young children and the elderly. Similarly, in Nicaragua, having introduced rotavirus vaccination, sapovirus was the second most commonly detected enteropathogen among children aged <5 years and was observed in 15% of hospitalizations due to gastroenteritis.

Clinical Features

Sapovirus infection manifests with typical viral gastroenteritis symptoms, characterized by vomiting, watery diarrhea and abdominal pain. Other symptoms, including fatigue, nausea, headache, myalgia and chills can also be present. The clinical picture is very similar to norovirus, but the symptoms tend to be milder than those of norovirus and rotavirus infections. Laboratory diagnosis is essential for virus detection. Similar to norovirus infection, there is usually no or low fever. The incubation period is 1–4 days, but asymptomatic cases have been reported. Although the person does not show symptoms, they are still shedding high amounts of infectious virus and are capable of spreading the virus through the fecal-oral route. In immunocompetent individuals, diarrhea is usually resolved within one week.

Pathogenesis

Knowledge of the pathogenesis and cell tropism of human sapovirus is limited due to a lack of a small-animal model. Pathological lesions have only been studied in pigs infected with porcine sapovirus, and visualization by histopathological staining showed that the virus infects cells of the small intestine. Tissue sections show histological changes with villus atrophy in the duodenum and/or jejunum of inoculated pigs at day 3–7 post infection. These results were confirmed by scanning EM which also revealed villi shortening, blunting, fusion, or absence of villi.

Cell Culture

None of the human sapoviruses had previously been propagated in cell culture. However, porcine enteric calicivirus (PEC) grows in primary porcine kidney cells and in a porcine kidney cell line (LLC-PK), in the presence of porcine intestinal contents or bile acids to permit virus replication. It was thought that the bile acid or intestinal contents support growth in vitro and in vivo by downregulating innate immunity, through cyclic AMP/PKA signaling, which downregulates STAT1 and antiviral interferon (IFN) signaling. However, sapovirus growth in cell lines deficient in their ability to induce or respond to IFNs showed a 100–150-fold increase in infectious virus production, indicating that the primary role of bile acids is not inactivation of the innate immune response. Although the addition of bile acids is an essential co-factor for porcine sapovirus replication in cell culture, the mechanism has yet to be fully elucidated.

Recently, the stem-cell derived HIE culture system was used for successful replication of human norovirus. After this historical success, the non-transformed cell culture system has been used for other human enteric viruses such as enterovirus, rotavirus, adenovirus type 41 and astrovirus. This human intestinal non-transformed cell culture method is being currently explored for cultivation of human sapovirus.

Immunity

Seroprevalence studies of human sapoviruses have demonstrated gradually increasing seroprevalence during the early years, reaching high levels in school-aged children that remain high in adults. Reinfection with the same genogroup is common, but is rare with the same genotype, suggesting that infection generates a genotype-specific immunity from each infection. The fact that sapovirus gastroenteritis occurs more frequently in young children than in older children and adults suggests that natural infection likely provides long term protection against sapovirus and provides hope for success of a possible future sapovirus vaccine.

In contrast to norovirus infection, sapovirus infection has not been associated with host HBGA phenotypes. Neither the fucosyltransferase 2 (Fut2)^{-/-} non-secretor mutation (428A) nor any of the ABO blood groups or Lewis phenotypes protected children against sapovirus-infection.

Diagnosis

Visually, sapoviruses are distinguishable from other gastroenteric viruses, except norovirus, by their ‘Star of David’ morphology in EM, but EM has low sensitivity. Enzyme-linked immunosorbent assay (ELISA) can be used for antigen detection of human sapovirus, but the method is less sensitive than the current commonly and routinely used RT-PCR methods. Due to the high genetic diversity of sapoviruses, primers targeting well-conserved regions, may also amplify other gastroenteritis viruses. Multiple primers are often used for detecting sapoviruses of different genogroups. Targeting the RdRp-VP1 junction region, the overlapping part of the RdRp and VP1 genes, has the highest detection rate and is often the first choice for screening of clinical samples. For genotyping, VP1-targeting primers are preferred, as they allow reliable genotyping of the sequenced PCR products, since the RdRp-VP1 junction region is too short and conserved for sequence analysis.

Prevention

Sapoviruses can be transmitted from person to person via contacts with sapovirus-positive feces, vomitus, or sapovirus-contaminated materials/surfaces, or via contaminated food and drinking water. Sapovirus, like norovirus, is probably transmitted efficiently by aerosol from vomiting. To date, no vaccines or antiviral drugs are available for preventing or treating human sapovirus infections.

Infectivity and stability testing of the porcine sapovirus has shown that the virus is stable at pH 3.0–8.0 at room temperature (RT) for 1 h, sensitive to ethanol treatment (60% and 70%) at RT for 30 s, inactivated by 200 mg/L (or ppm) sodium hypochlorite at RT for 30 min and inactivated by heating at 56°C for 2 h. The stability of human sapovirus needs to be further investigated.

This is an update of P.F. Lambert, A. Collins, Papillomaviruses: Molecular Biology of Human Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00458-1. and G. Orth, Papillomaviruses: General Features of Human Viruses, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy, Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:10.1016/B978-012374410-4.00457-X.

Taxonomy, Classification, and Evolutionary Relationships

Human papillomaviruses (HPVs) belong to the family *Papillomaviridae* that was established by the International Committee on the Taxonomy of Viruses in 2005 (previously, they had been classified with *Polyomaviridae* under the now defunct *Papovaviridae*). *Papillomaviridae* has two sub-families, the *Firstpapillomavirinae* and *Secondpapillomavirinae* (the latter contains only one genus). *Firstpapillomavirinae* are further classified into genera, based on nucleotide sequence homology of the L1 gene. Viruses with 61% or greater L1 nucleotide identity are considered to be within the same genus. *Firstpapillomavirinae* has 52 genera that are named by a Greek letter prefix.

Five genera from the *Firstpapillomavirinae* contain the human papillomaviruses: *Alpha*-, *Beta*-, *Gamma*-, *Mu*-, and *Nupapillomavirus*. Within each genus, viral genomes are further separated into species that share between 71% and 89% nucleotide identity within the L1 gene. For example, within the *Alphapapillomavirus* genus, the species are named α -1, α -2, α -3, etc. At the next level, viral genomes are divided into types and the L1 sequence of each type must differ > 10% from any other type. Within each type, there are usually distinct variant lineages. For example, the oncogenic virus HPV16 can be further separated into genetic lineages A1–4, B1–4, C1–4, and D1–4.

In the HPV community, a virus receives an official designation as a reference genome only if the complete viral genome has been sequenced and a viral genomic DNA clone has been sent to the HPV Reference Center in Sweden for validation. To date, reference genomes have been officially designated up to HPV226. However, an even greater number of additional novel HPV types have been identified and sequenced but have not been submitted to the HPV Reference Center. The sequences of these Non-reference genomes can be found in the Papillomavirus Episteme database (see “Relevant Websites” section). Fig. 1 shows a phylogenetic tree of the named reference HPV types found in the *Alpha*-, *Beta*-, *Gamma*-, *Mu*-, and *Nu*- genera.

Papillomaviruses are an ancient group of viruses that have co-evolved with their hosts for millions of years. When *Homo sapiens* emerged they were likely already infected with multiple ancestral HPV types related to those in the genera we recognize today. The HPVs have continued to slowly evolve, adapting to different anatomical and biological niches. Current thinking is that niche adaptation to susceptible host cells inadvertently led to the emergence of HPV-associated oncogenesis.

Virion Structure

HPVs have non-enveloped icosahedral capsids with $T = 7d$ symmetry and are approximately 55 nm in diameter. The capsid is composed of two proteins, L1, the major structural protein, and L2, the minor protein. Each capsid consists of 360 L1 proteins arranged into 72 pentamers (or capsomeres) and a variable number of L2 monomers (observed to range from 12 to 72 molecules). HPV particles are very stable, and are resistant to degradation by various chemical and enzymatic processes. The L1 proteins can self-assemble into Virus-Like Particles (VLPs), and these VLPs are the main components of the current HPV prophylactic vaccines (See Fig. 2).

The HPV capsid encloses a circular, double-stranded DNA genome of approximately 7–8 kbp in length. A relatively unusual feature of papillomaviruses is that the capsids package the viral DNA in the form of chromatin; host core histones organize the genome into a chromatinized minichromosome.

Genome

The circular dsDNA viral genome is organized into the following three parts: the upstream regulatory region (URR) contains elements that regulate transcription and replication; the early region contains genes expressed in the early and maintenance phases of infection; and the late region encodes the proteins expressed at late stages of the viral life cycle. Fig. 3 shows the genomic arrangement of an oncogenic Alpha-HPV genome.

All viral mRNA is expressed from one strand of the viral genome. In the oncogenic Alpha-HPVs, the early viral genes are transcribed from promoters located in the URR (just upstream from the early region) and terminate at the early polyadenylation site. An intermediate class of transcripts (that encode E1, E2, and E1E4) use the late promoter (located in the E7 open reading frame (ORF) in the oncogenic Alpha-HPVs) and terminate at the same early polyadenylation site. Finally, late transcripts initiate from the late promoter and terminate at the late polyadenylation site at the end of the coding region. Other HPVs have additional

promoters in the early coding region of the viral genome. The use of different viral promoters and polyadenylation signals results in a diverse assortment of polycistronic transcripts, many of which are further alternatively spliced, thus allowing efficient use of the limited coding capacity of the small genome.

All papillomaviruses contain four conserved open reading frames that encode two replication proteins, E1 and E2, and two capsid proteins, L1 and L2. All HPVs also express two additional proteins encoded from spliced transcripts: E8E2 is a truncated E2 protein that antagonizes the function of full-length E2 and E1E4 is an intermediate protein encoded primarily from an alternative open reading frame in the E2 gene. Almost all HPVs express E6 and E7 proteins. In addition, the oncogenic Alpha-HPVs (and those that are evolutionarily closely related) express a spliced E6 transcript, E6*. In the Alpha-HPVs, short, hydrophobic, transmembrane proteins (called E5) are encoded at the end of the early region. Sometimes more than one evolutionarily distinct E5-like protein is encoded in this region and they are named E5 α , E5 β , E5 γ , or E5 δ .

Host Range and Tissue Tropism

Papillomaviruses are highly species specific and tissue tropic. HPVs will only infect and replicate in the cutaneous and mucosal epithelial surfaces of *Homo sapiens*. HPVs enter and establish a persistent infection of keratinocytes and rely on the differentiation

Fig. 3 Viral genome. A genome map of the oncogenic Alpha-papillomavirus HPV18. The core early genes shown in green, and those encoding the late, capsid proteins in blue. The E4, E5, E6, and E7 genes are shown in purple. The URR (upstream regulatory region) contain transcriptional regulatory elements and the origin of replication (ori). The early and late promoters (P_E and P_L) and polyadenylation sites (pA_E and pA_L) are indicated.

Fig. 4 *Differentiation-dependent Life Cycle of Papillomaviruses.* The stages of the HPV lifecycle in a stratified epithelium. The virus enters the basal cells through a fissure in the epithelium and the genome replicates here at low levels. As the infected cells move up to the surface of the epithelium during the differentiation process, high levels of viral gene expression and genome amplification are induced. Viral particles assemble in the upper layers and are shed from the surface in squames.

program of these cells to support viral production. In addition, each HPV replicates in specific types or anatomical regions of the host epithelium. This tropism is not well understood and does not appear to be due to entry receptors; rather it is thought that each virus relies on specific cellular processes (e.g., transcription, tissue renewal, differentiation) to support the viral life cycle. Likely, the functions of the E5, E6, and E7 proteins of each HPV evolved to take advantage of these niches. Cancers of the cervix often arise at the transformation zone, which is the junction between squamous and columnar epithelial cells. Cells that reside here are especially susceptible to HPV-associated carcinogenesis.

Life Cycle

The HPV life cycle is intricately and inexorably tied to the differentiation program of the host keratinocyte (Fig. 4). In a stratified epithelium, only the basal cells divide. Keratinocyte division can occur symmetrically to produce two basal cells, or asymmetrically to produce one basal cell and a second daughter cell that differentiates and moves slowly towards the surface of the epithelium as part of the terminal differentiation process. Infection of the basal cells ensures that the viral genome is maintained for long periods of time and at the same time will continually yield cells that eventually produce progeny viral particles.

The different stages of viral replication and gene expression are temporarily and spatially regulated at the different stages of keratinocyte differentiation. Viral gene expression and DNA replication are very low in infected basal cells but are activated in suprabasal cells to amplify the viral genome to high levels. In even more differentiated cells, late viral gene expression produces the L1 and L2 proteins to package the viral genome and form infectious progeny virions. Compared to many viruses, the HPV infectious cycle is relatively long, with at least three weeks from initial infection to the first production of progeny virions.

Entry

The HPV life cycle begins when an infectious virion accesses the basal keratinocytes exposed by microabrasions in the host epithelium. The major L1 capsid protein initially interacts with heparin sulfate proteoglycans on the exposed basement membrane. Here, L1 is cleaved by Kallikrein-8 (KLK8), causing a conformational change in the capsid. Subsequent interaction with cyclophilin

Table 1 Functions of the HPV Proteins

<i>Protein</i>	<i>Function</i>
E1	Origin binding replicative helicase
E2	DNA binding protein; E1 helicase loader, transcriptional regulator, tethering and partitioning of viral genome
E8E2	DNA binding protein; repressor of viral transcription and replication
E1E4	Late protein; disrupts keratin filaments; aids virion release
E5	Regulates cell cycle, contributes to viral egress
E6	Immune evasion, manipulates cell pathways to produce a cellular environment conducive to persistent viral replication
E7	Immune evasion, manipulates cell pathways to produce a cellular environment conducive to persistent viral replication
L1	Major structural protein
L2	Minor structural protein, trafficking of viral DNA during entry, packaging viral DNA

B triggers a second conformational change in the virion, exposing a furin cleavage site in the minor capsid protein L2. Furin cleavage of L2 exposes the RIG-1 epitope and facilitates the transfer of the virion to an unknown secondary receptor on the basal keratinocyte. The viral particle is internalized by endocytosis and the low pH in the endosome, and the activity of cyclophilin B, causes L1 to disassemble from the particle, leaving a complex of the L2 protein and viral chromatin. L2 is inserted into the endosomal membrane resulting in virus containing vesicles that move through the trans golgi network. These vesicles enter the nucleus at the onset of mitosis when the nuclear membrane breaks down. They bind to condensed mitotic host chromosomes until cell division is complete.

Early Stages of Infection

After cell division is complete, the L2-viral minichromosome complex is released from the membrane vesicles and localizes to ND10 bodies to begin the early part of the life cycle. Many viruses associate with ND10 bodies early in infection, even though these bodies are thought to be involved in anti-viral defense. However, viruses often disrupt and reorganize ND10 bodies by displacing repressive components and taking advantage of positive factors. Similarly, the HPV L2 protein displaces the host Sp100 protein from ND10 bodies to promote a local nuclear environment conducive to early viral replication and transcription. The viral early promoter drives transcription of early genes, including those of the replication proteins E1 and E2. E1 and E2 bind the replication origin, unwind the viral DNA, and work in concert with the cellular DNA replication machinery to amplify the viral genome to a low copy number (just a few copies per cell). The new viral genomes establish a persistent infection by localizing to beneficial regions of the host nucleus that will support low level gene expression, and evade host defenses.

Maintenance Phase of Infection

During this phase of the life cycle, the late structural genes are not transcribed and no infectious particles are formed, thus it is dubbed the “non-productive” phase. To maintain a long term non-productive infection, the virus must keep a low immunogenic profile and faithfully pass the genome onto successive daughter cells as the basal keratinocytes proliferate. The E2 protein binds to sites in the viral genome and tethers the extrachromosomal viral genome to the host chromosomes. This ensures that the viral genome is retained in the nucleus and distributed to daughter cells in mitosis. In this way, the viral genome persists as a low copy extrachromosomal circular DNA.

Late Stages of Infection

When cells maintaining HPV genomes detach from the basement membrane and begin their journey upward through the epithelium, the virus begins the late (or “productive”) phase of its life cycle. In these terminally differentiating cells, expression of the viral E5, E6, and E7 proteins delay the normal keratinocyte differentiation program and disrupt cell cycle regulation. High levels of the E1 and E2 proteins induce massive amplification of the viral genome in differentiated cells that are in a G2-like phase. HPVs rely on the cellular DNA replication machinery to replicate viral DNA but this is not present in G2 phase or differentiated cells. Therefore, HPVs induce a DNA damage response and repair factors traffic to the viral genome to replicate viral DNA in nuclear foci using what is presumed to be recombination-directed replication mechanisms. Following this, transcription and translation of the late structural proteins L1 and L2 occur; these proteins assemble around chromatinized progeny genomes to generate infectious virions. Further maturation of the virions occurs in the oxidizing environment of the uppermost, dying keratinocytes. These cells, containing arrays of mature virions, are sloughed off the surface of the epithelium by desquamation. Prior activities of the E4 and E5 proteins increase the fragility of these squames, so that they will more easily release viral particles.

Functions of Individual Viral Genes (Table 1)

The E1 Protein

The E1 gene product is a sequence-specific origin binding replicative helicase that is essential for viral DNA replication. Homodimers of the E1 and E2 proteins initially bind cooperatively to their respective binding sites in the viral origin of replication. A conformational shift in the E1 protein displaces E2 and recruits additional E1 proteins to form a double hexamer, which is the functional replicative helicase that unwinds the DNA bidirectionally and allows cellular replication machinery to bind and process the template.

The E2 Protein

The viral E2 protein is multifunctional; it is involved in replication, transcription, and maintenance of the viral genome. E2 consists of an N-terminal transactivation domain linked by a flexible “hinge” sequence to the C-terminal DNA binding/dimerization domain. E2’s main role in initiation of replication is to assist in loading the E1 helicase onto the origin of replication, but it further contributes by displacing nucleosomes and recruiting cellular replication proteins. E2 additionally functions in maintenance replication by partitioning the viral DNA to daughter cells by tethering the genome to host chromatin. E2 is also the primary regulator of HPV transcription, functioning predominantly by recruiting cellular activating or repressing factors to promoters and enhancers in the viral genome through its E2 binding sites (E2BSs).

The E8E2 Protein

The E8E2 protein arises from a spliced transcript that encodes a short peptide from the E8 ORF fused to the C terminal DNA binding and dimerization domain of E2. E8E2 can competitively bind to E2 binding sites and recruits repressive cellular NCoR/SMRT complexes which restricts HPV transcription and replication.

The E1E4 Protein

The E4 protein is expressed as an E1E4 fusion protein from a spliced transcript encoding the first few codons of E1 joined to the E4 ORF. The resulting protein is a small, mostly cytoplasmic protein that interacts with a variety of cellular partners. Despite its location in the early region of the viral genome, high levels of E1E4 expression correlate with the start of productive viral DNA synthesis in the later stages of the life cycle, where it is among the most abundant protein of the infected cell. The exact role of E1E4 in viral genome replication is not fully understood. E1E4 induces G2/M cell cycle arrest by sequestering cyclins and cyclin dependent kinases, and interacts with many other cellular proteins. The major function of E1E4 may be its contribution to the release of progeny HPV virions by associating with and destabilizing cornified cell envelopes and keratin filaments, thus aiding virion egress from infected, desquamated cells.

The E5 Protein

The E5 proteins are small hydrophobic membrane proteins that are encoded only by the human Alpha-papillomaviruses (as well as many animal papillomaviruses). At the sequence level, there are several different types of E5 protein (named alpha, beta, gamma and delta) that are each evolutionarily distinct. For the most part, the oncogenic Alpha-HPVs encode alpha-E5 proteins and these are the best studied.

E5, together with E6 and E7, promotes proliferation of infected cells. Alpha-E5 proteins increase cell growth by enhancing the signaling capacity of the epidermal growth factor receptor (EGFR). Additionally, E5 forms a complex with the 16K subunit of the V-ATPase and this may impair keratinocyte cell-cell communication. E5 also hinders cellular antigen presentation by blocking HLA-I from trafficking to the cell surface and by inhibiting the maturation of MHCII. The alpha-E5 proteins encoded by oncogenic high-risk HPVs inhibit apoptosis and maintain the proliferative capacity of differentiating keratinocytes. Moreover, HPV E5 (along with E6) has been proposed to contribute to viral egress by inducing koilocytic vacuoles in the nucleus of infected cells, thus increasing cell fragility and aiding virion release from desquamated cells.

The E6 Protein

The E6 proteins contain two zinc finger domains linked together by an alpha helix. Together, these domains give E6 proteins the ability to interact with different cellular proteins that contain acidic, helical LxxLL motifs. The Alpha-HPV E6 proteins bind to the cellular E3 ubiquitin ligase, E6 Associated Protein (E6AP). In the oncogenic Alpha-HPVs this complex ubiquitinates p53, leading to p53 degradation by the proteasome and allowing the cell cycle to proceed with G1/S progression. This action by E6 to degrade p53 is required for the long-term maintenance of the viral genome. On the other hand, the Beta- and Mu-HPV E6 proteins bind LxxLL motifs on mastermind-like (MAML) proteins. MAML proteins are transcriptional coactivators for Notch signaling and inhibit the ability of Notch to promote squamous epithelial differentiation. The oncogenic Alpha-HPV E6 proteins contain a

C-terminal region that allows them to bind and degrade PDZ domain proteins involved in cell polarity. These E6 proteins also induce telomerase expression, allowing proliferating cells to escape senescence due to eroding telomeres. In contrast, many Beta-HPV E6 proteins increase tolerance to UV-mediated DNA damage and in this way could act as a cofactor in the development of squamous cell skin cancer. The multifunctional HPV E6 proteins also inhibit innate immune response pathways.

The E7 Protein

Almost all HPVs encode an E7 protein, a small early protein that binds multiple cellular targets. The main functions of E7 are to ensure that the cellular environment is favorable for HPV replication. In the high-risk Alpha-HPVs, the E6 and E7 proteins manipulate the cell in such a way as to promote genetic instability and oncogenic progression of the infected cell are thus considered to be oncogenes. For example, high-risk E7 promotes cell cycle progression by binding and degrading the tumor suppressor retinoblastoma protein (pRb), thus overriding its ability to inhibit the progression of the cell cycle from G1 into S phase and promoting cellular proliferation. This stabilizes p53, which in turn is degraded by high-risk E6. E7 also causes global, epigenetic reprogramming by upregulating Lysine Demethylase 6 (KDM6) A and B. E7 also induces cellular DNA damage signaling to promote viral DNA amplification in differentiated cells. Similar to the E6 proteins, E7 proteins inhibit the host innate immune responses.

The L1 Protein

L1 is the major structural protein of the HPV capsid. The L1 protein forms pentamers called capsomeres, and 72 of these self-assemble into an icosahedral particle with $T = 7$ symmetry. The L1 protein is sufficient to form virus-like particles (VLPs). L1 initiates the infection process by binding to the extracellular matrix (ECM) at the base of a stratified epithelium, and then facilitates entry of the virion into the cell by interaction with a secondary receptor on the basal keratinocyte. While most of the L1 dissociates from the viral genome throughout the trafficking to the nucleus, some L1 remains associated with HPV DNA. In the late stage of the viral life cycle, L1 is expressed in the uppermost layer of the epithelium where, together with L2, it encapsidates viral DNA to produce progeny virions.

The L2 Protein

L2 is the minor capsid protein and it has several important functions during viral entry and trafficking of the viral genome to the nucleus. After endocytosis, L2 becomes transmembranous and redirects the viral genome complex to the nucleus in a membrane vesicle via the retromer pathway. When the infected cell undergoes mitosis, the L2-genome containing membrane vesicle associates with host mitotic chromosomes. After the nuclear envelope reforms, the viral complex localizes to the ND10 nuclear bodies. Here, L2 displaces Sp100, a restriction factor of HPV, to facilitate an environment conducive to viral transcription. At late stages of infection L2 is expressed in the upper layers of the epithelium where it assists in packaging of the viral genome.

Natural History, Transmission and Epidemiology

HPVs are ubiquitous and, in most cases, cause asymptomatic or transient, self-limiting infections. The viral particles are very stable and are released from the desquamating surface of infected epithelia. Transmission of cutaneous types are by direct host to host contact, or through contact with a contaminated surface. Anogenital and oral HPV types are usually transmitted by sexual contact. In both cases, the virus enters the epithelium and accesses the basal epithelial cells through small scratches or microabrasions.

HPV infection is extremely common. Children and adolescents have the highest prevalence of warts of the hands and feet, and a high proportion of individuals become infected with anogenital HPVs when they become sexually active. In most cases, the infections are self-limiting and regress without treatment. However, individuals persistently infected with oncogenic HPV types are at risk of progression to cancer. Widespread vaccination with the current HPV vaccine can prevent infection with the most common oncogenic types.

Clinical features, Pathogenesis and Histopathology of HPV Infection

There are hundreds of different HPV types and they each infect different regions of the cutaneous epithelium (skin), the anogenital mucosal epithelium, and the epithelium of the oral cavity. These infections give rise to common, plantar, flat plane or anogenital warts (papillomas). Lesions and pre-cancers are also found in the oral cavity and anogenital regions. Many HPV types (in particular those from the Beta and Gamma genera) persist asymptotically in the cutaneous epithelium, resulting in lesions only in individuals with immunodeficiencies.

The cell layers of the epithelium are greatly expanded in many common warts resulting in exophytic lesions with rough, cauliflower-like appearances. Plantar warts (verruca) are endophytic and infected cells grow deep into the sole of the foot. Plane warts present as flat papules on cutaneous skin surfaces. These warts often show characteristic histological features of acanthosis

(thickening of the epithelium), parakeratosis (nuclei retained into the cornified layer), and hyperkeratosis (a thickened cornified layer). Lesions often contain koilocytes, which are cells with shrunken hyperchromatic nuclei that are displaced by a large perinuclear vacuole. The presence of koilocytes is usually indicative of HPV infection. Anogenital warts (condyloma acuminata) present as discrete, small papules on the genital regions. Laryngeal papillomatosis (recurrent respiratory papillomatosis) is a rare condition associated with low-risk HPV infection (possibly due to an unidentified immunodeficiency). Here, benign papillomas form in the respiratory tract and tend to recur despite multiple surgeries.

Oncogenic HPVs

A subset of Alpha-papillomaviruses are associated with cancer. The E6 and E7 proteins (oncogenes) of these viruses promote unscheduled cellular proliferation and inactivate cell cycle checkpoints. This leads to genetic instability as infected cells accumulate mutations that promote carcinogenesis. Infection with oncogenic HPVs is extremely common and most infections resolve without treatment. Only long term, persistent infection with oncogenic HPVs is associated with oncogenic progression.

The International Agency for Research on Cancer (IARC) has reported that 13 Alpha-HPVs are oncogenic and that close, evolutionarily related types are “probably” oncogenic. [Fig. 1](#) shows a phylogenetic tree of human papillomaviruses with the oncogenic Alpha-HPVs indicated in red.

In many cancers associated with HPV infection, the viral genome is integrated into the host chromosomes. Integration is not part of the normal viral life cycle and is a dead end for virion production. The only viral proteins consistently expressed in cancers are the E6 and E7 oncogenes. It is thought that the viral genome accidentally integrates into regions of the host genome that promote dysregulated expression of the E6 and E7 oncoproteins. The resulting increase in cellular proliferation, absence of cell cycle checkpoints, and promotion of genomic instability drives infected cells toward oncogenesis.

HPV-associated Cancers

About 5% of human cancers can be attributed to oncogenic Alpha-HPV infection. Persistent HPV infection is the causative agent of almost all cancers of the uterine cervix and the majority of vaginal, vulvar, penile, anal and rectal cancers. A large proportion of oropharyngeal cancers are also due to HPV infection. Beta-HPVs cause asymptomatic infection of the skin and are often found in squamous cell carcinomas. However, they are not essential for the maintenance of the tumors and may play a role in the development of cancer by impairing the repair of UV damage. Conversely, these infections may also enhance CD8⁺ T cells anti-tumor activity and suppress cancer.

Immune Response

HPVs must avoid host immune defenses and the virus replication cycle itself is a strategy of immune evasion. There is no viremia or cell lysis associated with HPV infection and high levels of viral genome replication, transcription and protein synthesis are confined to terminally differentiated cells. Viral particles are shed from the surface of the epithelium and so do not induce an immune response. The virus also suppresses interferon and other cytokine responses and downregulates innate immune sensors.

Most infections are self-limiting and regression is due to a cell-mediated immune response. Infection does not always lead to seroconversion and levels of natural antibodies to HPV antigens are low. This is in contrast to the immune response to HPV vaccines, which induce extremely high levels of anti-L1 neutralizing antibodies. The levels of these antibodies contained in serum exuded at epithelial microabrasions are sufficient to prevent infection.

However, HPV infection is not completely invisible to host immune defenses as evidenced by the great increase in pathogenic HPV lesions and cancers in cases of immunosuppression and immunodeficiency. Individuals with uncontrolled HIV infection, or immunosuppressed organ transplant recipients, often have prolific HPV disease. Some genetic primary immunodeficiencies also give rise to uncontrolled HPV infections. For example, individuals with WHIM syndrome (Warts, Hypogammaglobulinemia, Infections, and Myelokathexis) are very susceptible to HPV warts, but treatment of the underlying immune defect results in resolution of HPV lesions. In the rare genetic disease Epidermodysplasia verruciformis, Beta-HPVs that usually cause asymptomatic infections in healthy individuals give rise to plaques of HPV infection on the cutaneous epithelium with a high propensity to develop into squamous cell carcinomas on UV-exposed skin.

Diagnosis

Dermatologists and gynecologists diagnose common, plantar, plane and genital warts from clinical and histological appearance; evaluation of HPV type is usually unnecessary. However, because cervical HPV infections are common (and can lead to pre-cancerous and cancerous lesions), a routine gynecological exam incorporates a Pap smear (invented by George Papanicolaou). In this test, cells are brushed from the surface of the cervix and analyzed by cytopathologists for signs of HPV infection or other abnormalities. For follow up, cervical (or anal) pre-cancerous lesions are treated in situ with acetic acid so that they can be visualized by colposcopy or anoscopy. Small biopsies of these lesions are further analyzed histologically to determine the stage of cervical or anal squamous intraepithelial lesions (ASIL or CSIL). HPV types that infect the anogenital region can be classified as

“low oncogenic risk” or “high oncogenic risk” and tests are available to determine the HPV DNA type and thus the relative risk of disease progression.

Treatment

HPV infections are very common, and in most healthy individuals are self-limiting and require no treatment. If bothersome, common warts of the hands and feet can be treated with salicylic acid (available as over-the-counter treatments). Topical application of creams containing imidazoquinoline-based IRMs (Immune Response Modifiers) can enhance the host immune response and induce regression of various types of warts. Persistent pre-cancerous lesions of the cervix are removed by ablation techniques such as laser vaporization, cryotherapy or LEEP (loop electrosurgical excisional procedure), while HPV associated cancers are treated by surgery, chemotherapy, and radiotherapy.

Prevention

Vaccination with prophylactic HPV vaccines is the most effective means of prevention. To date, three highly effective vaccines have been developed against the most common HPV types that cause anogenital infection and associated cancers. Each of these vaccines contains the HPV L1 protein, self-assembled into VLPs (Virus-Like Particles) and an adjuvant. Cervarix contains HPV16 and HPV18 VLPs, Gardasil-4 contains HPV6, 11, 16, and 18 VLPs, and Gardasil-9 contains HPV6, 11, 16, 18, 31, 33, 45, 52, and 58. The VLPs are extremely immunogenic and when delivered intramuscularly induce high titers of neutralizing antibodies. The efficacy of these vaccines in preventing warts and cancer precursor lesions in the anogenital region is excellent and there is hope that in countries with high rates of vaccination uptake, HPV-associated cancers could eventually be eliminated.

Human Parainfluenza Viruses (*Paramyxoviridae*)

Elisabeth Adderson, St. Jude Children's Research Hospital, Memphis, TN, United States and University of Tennessee Health Sciences Center, Memphis, TN, United States

© 2021 Elsevier Ltd. All rights reserved.

This is an update of E. Adderson, A. Portner, Parainfluenza Viruses of Humans, In Encyclopedia of Virology (Third Edition), edited by Brian W.J. Mahy and Marc H.V. Van Regenmortel, Elsevier Ltd., 2008, doi:[10.1016/B978-012374410-4.00459-3](https://doi.org/10.1016/B978-012374410-4.00459-3).

Classification

The family Paramyxoviridae, in the order Mononegavirales, consists of large negative-sense, single-stranded, enveloped RNA viruses belonging to 4 subfamilies and 14 genera. The 4 human parainfluenza viruses (HPIVs) belong to 2 separate genera within this family. HPIV-1 and HPIV-3, as well as bovine, murine, and porcine parainfluenza viruses, are members of the Respirovirus genus. HPIV-2 and HPIV-4 are members of the Orthorubulavirus genus, which also includes mumps virus and several pathogens of non-human mammalian species. HPIV-4 is further divided into two subtypes, HPIV-4a and HPIV-4b, on the basis of serologic reactivity.

Virion Structure

HPIVs are roughly spherical viral particles 150–250 nm in diameter consisting of a host-cell plasma membrane–derived lipid bilayer surrounding an 18-nm diameter internal helical nucleocapsid containing the negative-sense, non-segmented, single-stranded RNA genome. Projecting from the surface of the virion are 2 transmembrane glycoproteins, hemagglutinin–neuraminidase (HN) and fusion (F) protein. These glycoproteins are anchored to the plasma membrane of the infected cell or the virion envelope by a hydrophobic transmembrane region. A schematic representation and an electron micrograph of a naturally occurring parainfluenza virus (PIV) are shown in [Fig. 1](#).

Genome

The genomes of HPIVs range from 15,400–17,000 nucleotides and encode 6 common structural proteins, linked in tandem in the order 3′-nucleocapsid protein (NP)–phosphoprotein (P)–matrix protein (M)–F–HN–large protein (L)–5′. In general, the genome organization of HPIV is remarkably similar, but differences exist in gene sequences, intergenic regions, and nonstructural proteins expressed from the P gene. Sequence and immunological analyses suggest that human HPIV-1 and murine Sendai virus are closely related, as are human- and bovine-origin PIV-3 [Fig. 2](#).

The RNA nucleocapsid, a complex consisting of approximately 2000 molecules of NP bound to the RNA genome, rather than the RNA genome itself, serves as a template for RNA synthesis. The viral RNA-dependent RNA polymerase complex consists of a heterocomplex of about 200 P and 20 L molecules. The P gene is unique in its capacity to express not only P protein but also alternative proteins. This varying expression is determined by either use of internal initiation codons in the same or different reading frames or by insertion of non-templated G residues during the editing of the P gene specific mRNA. These alternative proteins have been designated V, C, and D, depending on the PIV. The approximate molecular weights in Daltons (Da) of the HPIV proteins, as exemplified by HPIV-3, are as follows: NP (58,000 Da); P (68,000 Da); M (40,000 Da); F (63,000 Da); HN (72,000 Da); and L (256,000 Da) [Table 1](#).

Life Cycle

HPIV replication starts in ciliated respiratory epithelial cells, initially in the nose and throat, and may subsequently progress to affect ciliated and alveolar cells of the lower respiratory tract. Infection is initiated by the attachment of viral particles to the host cell, the energy-dependent fusion of the viral envelope and target cell membrane, and the formation of pores through which the viral genome is introduced into the cell. The HN and F glycoproteins cooperatively mediate the direct binding of the virion to sialic acid–containing glycoprotein or glycolipid receptors on upper and lower respiratory tract epithelial cells. The same process is responsible for the hemagglutination of avian and mammalian erythrocytes. HN also causes the enzymatic (neuraminidase) cleavage of sialic acid residues from the carbohydrate moiety of glycoproteins and glycolipids, which functionally serves to prevent the self-aggregation of virus during release and likely aids in the spread of virus from infected cells. HN possesses an N-terminal stalk region of approximately 130 amino acids anchoring a large glycosylated hydrophilic globular head region to the viral envelope. A small uncharged hydrophobic peptide near the N-terminus spans the viral envelope, and a small hydrophilic domain is internal to the membrane. The globular head contains the active site for virus attachment, neuraminidase activity, and antigenic determinants that induce neutralizing antibodies for HPIVs. HN exits on the surface of the virion as disulfide-linked dimers of homodimers [Fig. 3](#).

Fig. 1 HPIV genome. The genome consists of 6 common structural proteins, linked in tandem in the order 3'-nucleocapsid protein (NP) – phosphoprotein (P) – matrix protein (M) – fusion protein (F) – hemagglutinin-neuraminidase (HN) – and large protein (L) – 5'.

Membrane proteins

- **HN**: receptor-binding, neuraminidase, fusion promotion
- **F**: membrane fusion
- **M**: assembly

Nucleocapsid

- **NP**: encapsidate viral RNA
- **P**: forms polymerase complex with L
- **L**: RNA synthesis, capping, polyadenylation

Fig. 2 Parainfluenza virus structure.

Table 1 HPIV-3 proteins

Name	Function	Size (Da)
Nucleocapsid protein (NP)	Structure, RNA binding	58,000
Phosphoprotein (P)	RNA-directed RNA polymerase	68,000
Matrix protein (M)	Structural, virion assembly	40,000
Fusion protein (F)	Fusion of virus membrane with host cell membrane	63,000
Hemagglutinin-neuraminidase (HN)	Viral attachment and entry into host cell, sialidase	72,000
Large protein (L)	RNA-directed RNA polymerase	256,000

Besides being needed for attachment, HN is essential to or enhances the fusion activity of the F protein. F proteins are class I fusogenic viral proteins that are synthesized as inactive precursors, then post-translationally cleaved by a host cell trypsin-like protease to form prefusion homotrimers. Following receptor binding, a conformational change in HN activates the F protein, triggering the insertion of hydrophobic membrane attack domains into the target cell membrane. The cell and viral membranes are then approximated by refolding of F into a hairpin structure. Membrane fusion precedes the formation of a pore through which the viral nucleocapsid is deposited into the host cell cytoplasm.

After the infecting nucleocapsid is introduced into the host cell, the polymerase complex transcribes viral mRNAs and initiates genome replication by generating an intermediary positive-sense RNA antigenome template. HN and F proteins are synthesized, post-translationally modified, and transported to the host cell membrane, which becomes the envelope for progeny virions. Once protein synthesis is underway, N protein encapsulates newly synthesized genomes that, in association with P, form new nucleocapsids that are also transported to the cell plasma membrane. The M protein lines the inner surface of the viral envelope. During infection, M associates with the inner leaflet of the plasma membrane, where it orchestrates the release (budding) of progeny virus into the respiratory tract lumen by interacting with specific sites on the cytoplasmic tail of the viral glycoproteins and the nucleocapsid and by transporting viral components to the budding site. HN facilitates the release of new virus particles by cleaving sialic acid residues on the host cell membrane.

Embryonated hen's eggs can support the growth of some strains of HPIV-1, HPIV-2, and HPIV-3. All 4 HPIV types grow well in primary monkey or human kidney cells, which are also used to isolate virus from clinical samples. LLC-MK2, a rhesus monkey kidney cell line, offers an efficient system for isolating PIVs and an experimental tissue culture system. HPIV-2 and HPIV-1 require trypsin in the medium to cleave the F glycoprotein for cell growth. Viral infection of tissue culture can be detected by hemadsorption with chicken and guinea pig erythrocytes and by the cytopathic effects produced by the viruses.

Epidemiology

The HPIVs are important causes of upper and lower respiratory tract infections worldwide (Table). Between 25%–40% of HPIV detections are in children aged 2 years or younger; and half are in children aged 7 years or younger. By 5 years of age, almost all persons have serological evidence of HPIV-3 infection, and 75% have been exposed to HPIV-1. HPIV-2 infection, but not infection

Table 2 Epidemiological and Clinical Features of HPIV

	<i>Infections</i>	<i>Seasonality</i>
HPIV-1	Croup Other URTI ^a Pneumonia in young infants, elderly adults	Autumn, biannual in odd-numbered years
HPIV-2	Croup Other URTI ^a Pneumonia in young infants, elderly adults	Autumn, biannual in even-numbered years
HPIV-3	Bronchiolitis, pneumonia in young infants, elderly adults Severe respiratory infection in immunocompromised patients Croup Other URTI ^a	Spring-summer, annual
HPIV-4	Other URTI ^a Pneumonia in young infants	Autumn, annual

^aOther URTI includes rhinitis, pharyngitis, sinusitis, otitis media.

due to other HPIVs, is more common in males. In the United States, HPIV-1 and HPIV2 infections generally peak in the autumn of alternate years (odd- and even-numbered, respectively), whereas HPIV-3 infections are more common in the spring and summer. The circulation of HPIV-4 infections has been less well studied, but detections appear to peak annually in the winter time. Overall, HPIV-3 is the most commonly detected HPIV, followed by HPIV-1, HPIV-2 and, lastly, HPIV-4. The simultaneous detection of more than one HPIV in an individual is unusual, but about one-third of HPIV are co-detected with other respiratory viruses, most commonly with rhino- and enteroviruses and influenza. Reinfections are possible, but generally cause milder disease than primary infection does. Outbreaks in healthcare and long-term care settings have been reported [Table 2](#).

Clinical Features

HPIVs are highly communicable and are transmitted person-to-person by respiratory droplets and by direct contact with e.g., hands and surfaces contaminated by respiratory secretions. The incubation period is 2–6 days; persons are most contagious in the early stages of infection. Virus is typically shed for 4–21 days, longer in children than in adults. Infections can cause rhinitis, pharyngitis, otitis media, sinusitis, infectious laryngotracheobronchitis (croup), bronchitis, bronchiolitis, and pneumonia. Less common manifestations include apnea, febrile seizures, aseptic meningitis, encephalitis, parotitis, pericarditis, myocarditis, disseminated infection, and Guillain-Barré syndrome. Although most infections are mild and self-limited, severe disease may occur in young children, the elderly, and immunocompromised persons. HPIVs are responsible for about 7%–17% of pediatric hospitalizations for febrile or acute respiratory infections. Certain serotypes are associated with specific clinical syndromes: notably

HPIV-1 and HPIV-2, with infectious laryngotracheobronchitis (croup), and HPIV-3, with bronchiolitis and pneumonia in infants. HPIV-4 causes milder disease than other HPIV types do. HPIV, particularly HPIV-3, may cause severe and protracted infections among persons with cellular immunodeficiencies. Rates of progression of upper respiratory tract infection (URTI) to lower respiratory tract infection (LRTI) may be up to 40% in patients with combined immunodeficiency and recipients of hematopoietic stem cell transplants and reported mortality rates range from 10% to 40%. HPIV LRTIs are associated with allograft dysfunction and rejection among lung transplant recipients and cryptogenic organizing pneumonia and persistent airflow obstruction in hematopoietic stem cell recipients, particularly those with graft-versus-host disease. Secondary bacterial and fungal infections may complicate HPIV, and these co-infections are associated with increased morbidity and mortality. HPIV infections may also trigger exacerbations of reactive airways (asthma), chronic obstructive pulmonary disease, and post-infectious olfactory dysfunction.

HPIV-1 and HPIV-2 cause 60%–75% of croup in pediatric outpatients in the United States, resulting in up to 65,000 hospitalizations annually. The illness, which is most common in children aged 6 months to 2 years, is characterized by inflammation of the larynx and trachea, subglottic edema, and airway obstruction. Children typically present with inspiratory stridor and barking cough, generally preceded by a brief history of coryza or other upper respiratory symptoms. Respiratory failure develops in up to 3% of affected children, but mortality is rare.

Pathogenesis

HPIVs bind to specific sialic acid-containing receptors on upper respiratory tract epithelial cells. The virus and host factors contributing to disease pathogenesis are not completely understood. Both viral (F and HN structure) and host features (genetic susceptibility, host cell proteases, immunocompetence, previous infection) are likely to influence the severity of infection. Viral shedding is prolonged, and disease is more severe in persons with T-cell immunodeficiencies, implying that cellular immunity is important in the control of an acute infection. Severe infection occurs following the spread of the infection to the lower respiratory tract. HPIV has direct cytopathic effects, causing ciliary damage, epithelial necrosis, and recruitment of a mononuclear inflammatory response. Recent studies suggest that host inflammatory responses, rather than the direct effects of viral replication, are important determinants of the severity of signs and symptoms of HPIV infection. Alterations in HN receptor binding or activity may influence host inflammatory responses independent of viral replication or the ability to infect epithelial cells. Infection may also trigger long-term bronchial hyperreactivity in genetically susceptible persons.

HPIV infection triggers cellular and innate responses that reduce viral replication and the persistence of virus in the respiratory tract. Protection from reinfection is associated with the development of serum and secretory antibodies against F and HN. Local IgA responses appear to be particularly important for sustained immunity. Various HPIVs can interfere with host immune responses by inhibiting interferon responses, for example by the accessory C protein. HPIVs share certain antigenic determinants, but structural and antigenic variation occurs between serotypes and, to a lesser degree, within strains belonging to the same type. Antigenic diversity is not generally progressive but may contribute to the propensity of HPIV to cause recurrent infections. The duration of protection after acute illness is relatively short, especially in infants, and protection from infection by heterotypic strains is incomplete.

Diagnosis

The gold standard for diagnosis of HPIV infections is culture on primary monkey kidney cells, human embryonic kidney cells, or human lung carcinoma cells, but this process is labor-intensive and slow, requiring incubation for 4–7 days. Nucleic acid amplification tests (NAATs), performed as single assays or as components of multiplexed respiratory panels, are several-fold more sensitive than is culture and are the diagnostic testing modality of choice where available. The sensitivity and specificity of these assays is >95%. Recent study results suggest a potential role for quantitative viral load testing to identify patients at high risk of disease progression or poor outcomes. Antigen testing and enzyme immunoassays have also been developed for HPIV diagnostics; these methods are rapid but less sensitive and specific than NAATs are. Appropriate samples for diagnostic testing include nasal or nasopharyngeal washes or swabs and bronchoalveolar wash fluid. Detecting specific IgM and IgG in paired acute and convalescent sera has limited utility in diagnosing acute infections, but these approaches are useful in research and epidemiological studies.

Treatment and Prevention

Most HPIV infections are mild and self-limited. Treatment is mainly supportive, concentrating on the provision of adequate hydration and supplemental ventilatory support, if needed. Oral or intramuscular corticosteroids reduce airway edema and reduce the duration and severity of symptoms and the risk of respiratory failure in children with croup. Nebulized epinephrine may have similar effects of short duration. Bronchodilators may be useful in patients with wheezing. In immunocompromised patients with severe infections, reductions in immunosuppressive therapy should be considered if feasible. Some experts also recommend using intravenous gammaglobulin in this population, especially those with hypogammaglobulinemia, although its efficacy in this setting is unproven. No licensed antivirals active against HPIV are currently available. Although ribavirin, a synthetic

guanosine analog, has in vitro activity against HPIV, it has not been effective in reducing the progression of URTI to LRTI or in reducing mortality in immunocompromised patients. DAS181 is a recombinant sialidase fusion protein that inhibits HPIV replication by removing cell-surface sialic acids. In early-phase clinical trials of inhaled DAS181 in immunocompromised patients with severe HPIV pneumonia, treatment was well-tolerated and appeared to reduce morbidity; a phase III trial is ongoing. Other antiviral therapies in development include selective inhibitors of HN, fusion, and IMP dehydrogenase and small-molecule inhibitors of RNA polymerase. Adoptive T-cell transfer using donor lymphocytes specific for HPIV is another strategy being investigated for use in severely immunocompromised patients.

Paramyxoviruses are labile and readily inactivated by heat, organic solvents, detergents, light, and low pH. Droplet and contact infection prevention precautions are appropriate in the health care setting. Despite considerable effort, no licensed vaccines to prevent HPIV exist. Early formalin-inactivated vaccines were poorly immunogenic and were scrutinized because of the potential of similarly designed vaccines for respiratory syncytial virus to enhance pulmonary inflammatory responses to infection with wild-type virus. Vaccines currently in early clinical trials include live attenuated HPIV-3 and HPIV-2, bovine PIV-3, human-bovine chimeras, bovine PIV or Sendai virus expressing heterologous HPIV F and HN proteins, and oligomannose-coated liposomal HN. These vaccines have, in general, been safe and immunogenic, although multiple doses are likely to be required, and immunity may be incomplete or of short duration.

Human Pathogenic Arenaviruses (*Arenaviridae*)

Sheli R Radoshitzky, United States Army Medical Research Institute of Infectious Diseases, Frederick, MD, United States

Juan C de la Torre, The Scripps Research Institute, La Jolla, CA, United States

© 2021 Published by Elsevier Ltd.

History and Classification

The first arenavirus, lymphocytic choriomeningitis virus (LCMV), was isolated in 1933 from a suspected case of St. Louis encephalitis. Shortly after LCMV was found to cause aseptic meningitis in humans, and the house mouse was identified as its natural reservoir. By the late 1960s the *Arenaviridae* family was recognized to include a group of viruses that shared with LCMV common morphology, serology, biochemical features, and a natural history of establishing long-term chronic infections in their natural rodent hosts. The pathogenic potential of arenavirus infections in humans was underscored with the discovery of Junín virus (JUNV) in the late 1950s as the causative agent of Argentinian hemorrhagic fever (AHF), and the subsequent identification of Machupo virus (MACV) and Lassa virus (LASV) in 1962 and 1969 as the etiologic agents of Bolivian hemorrhagic fever (BHF) and Lassa fever (LF), respectively. In the following years, additional pathogenic arenaviruses were discovered, including Guanarito (GTOV), Sabiá (SBAV), and Chapare (CHAPV) viruses in South America, and Lujo virus (LUJV) in Africa. During the last decade the use of the new technologies of deep sequencing and genome discovery has resulted in the discovery of many new arenaviruses, but their contribution to human disease remains to be determined. Notably, arenaviruses have been also discovered in reptiles (snakes) and fish, representing a significant expansion of the host range of arenaviruses.

Current arenavirus classification is based on pairwise sequence comparisons (PASC) of coding-complete genomes. Based on the most current sequence dataset, S segment and L segment nucleotide sequence identities for viruses within the same genus need to be higher than 40% and 35%, respectively. This analysis and additional characteristics, such as genome architecture, host range, modes of transmission and/or sites of replication in the cell, led to the establishment of four genera within the family *Arenaviridae*: *Antennavirus*, *Hartmanivirus*, *Mammarenavirus*, and *Reptarenavirus*. The hosts of mammarenaviruses are rodents, with the exception of Tacaribe virus (TCRV) that has been found in phyllostomid bats and ixodid lone star ticks. Reptarenaviruses and hartmanivirus infect reptilian hosts, and these infections can cause boid inclusion body disease (BIBD). Antennaviruses have a piscine host. Based on antigenic properties, mammarenaviruses have been divided traditionally into two distinct groups. Old World (OW) mammarenaviruses ("Lassa–LCMV serocomplex") include viruses indigenous to Africa and the worldwide distributed LCMV, whereas New World (NW) mammarenaviruses ("Tacaribe serocomplex") include viruses indigenous to the Americas. This classification is largely consistent with phylogenetic data and murid rodent host phylogeny, with OW mammarenaviruses infecting murid rodents primarily in Africa and NW mammarenaviruses infecting cricetid rodents primarily in the Americas.

This article focuses on arenaviruses known to cause disease in humans, all of them within the *Mammarenavirus* genus.

Mammarenavirus Virion Structure

Mammarenavirions are pleomorphic, ranging in size from 40 to more than 200 nm in diameter, with dense lipid envelopes. The virion's surface is decorated with evenly spaced spike projections composed of heterotrimer complexes of the viral glycoproteins GP1 and GP2 and the stable signal peptide (SSP) (Fig. 1(A)). Cryo-EM studies have shown that surface GP complexes are aligned with subagent Z and ribonucleoprotein (RNP) densities, which are packed into a two-dimensional lattice at the inner surface of the viral membrane. Virions contain the L and S RNP complexes organized in circular configurations. The L and S genomic RNAs are not present in equimolar amounts within virions (L:S ratios ~ 1:2), and low numbers of both L and S antigenomic RNAs are also present within virions. In addition, host ribosomes are documented to be incorporated into virions, but the biological significance of this incorporation remains uncertain.

Mammarenavirus Genome Organization and Proteins

Mammarenaviruses have a bi-segmented negative-stranded RNA genome (Fig. 1(B)). Each genome segment, L (large, 7.3 kb) and S (small, 3.5 kb) uses an ambisense coding strategy to direct the synthesis of two proteins from two non-overlapping open reading frames (ORF) of opposite polarities that are separated by non-coding intergenic regions (IGRs). The S RNA encodes the viral NP and the glycoprotein precursor (GPC), whereas the L RNA encodes for the viral RNA dependent RNA polymerase (RdRp) (L protein) and the matrix Z protein.

Mammarenavirus genomes exhibit high degree of sequence conservation at their 3'-termini and similarly to other viruses with segmented negative strand (sNS) RNA genomes, they exhibit 5'- and 3'-inverted complementary sequences at their L and S genome segments that are predicted to form panhandle structures. This prediction is supported by EM data showing the existence of circular RNP complexes within arenavirions. For several arenaviruses, a non-templated G residue has been detected at the 5' end of progeny genomic RNAs during replication. The IGRs are predicted to fold into stable hairpin structures. Transcription of the

Fig. 1 A. Schematic illustration of an arenavirus particle. Shown is the pleomorphic shape of the enveloped virion particle decorated by spikes composed of heterotrimers of GP1 and GP2 associated with the SSP (not shown in the figure). The surface glycoproteins are aligned with subjacent matrix Z protein that serves also as a bridge between the surface glycoproteins and the S and L vRNP complexes inside the particle. Each vRNP consists of the NP (red) and L polymerase (blue) together with the S or L genome RNA species. Mammarenavirus virions are thought to incorporate ribosome particles. B. Mammarenavirus genome organization. Each genome segment uses an ambisense coding strategy to direct the synthesis of two different proteins in opposite direction and separated by a non-coding intergenic region (IGR) that serves as a bona fide transcription termination signal. The S segment encodes for the virus NP and GPC precursor, whereas the L segment encodes for the L polymerase and the matrix Z protein.

S-derived NP and GP mRNAs was shown to terminate at multiple sites within the predicted distal stem of the IGR, supporting the view that a structural motif rather than a sequence-specific signal promotes the release of the arenavirus polymerase from the template RNA. There are significant differences in sequence and predicted folded structure between the S and L IGRs, but among isolates and strains of the same arenavirus, the S and L IGR sequences are highly conserved. In addition to their role in control of transcription termination, IGRs have been shown to play a critical role in production of infectious particles.

GPC is co-translationally cleaved by the signal peptidase to generate a 58-amino acid stable signal peptide (SSP), and post-translationally processed by the cellular protease subtilisin kexin isozyme-1 (SKI-1)/ site 1 protease (S1P) to generate the mature virion surface glycoproteins GP1 and GP2. GP1, GP2 and SSP form the GPC complexes that decorate the surface of virions and mediate virus receptor recognition and cell entry. GP1 mediates virion interaction with host cell-surface receptors, whereas GP2 directs fusion of virus and host cell membranes. The fusion process depends on a low pH-driven conformational change of GP2 from a metastable prefusion structure to a more stable postfusion six-helix bundle. Notably, the SSP contributes to trafficking and processing of GPC as well as to the GP2-mediated pH-dependent fusion process.

NP is the most abundant viral polypeptide both in infected cells and virions. It is the main structural component of the viral RNP responsible for directing RNA genome replication and gene transcription. The C-terminus of NP exhibits a type I interferon (IFN-I) counteracting activity. Crystallographic studies identified distinct N- and C-terminal domains within NP of LASV, LCMV and JUNV, features that are expected to be present in other mammarenavirus NPs. The N-terminal domain of NP contains an RNA-binding site and plausible cap-binding activity. The C-terminal part of NP contains a functional DEDDH 3'-5' exoribonuclease folding domain similar to the one described for the non-structural 14 protein of severe acute respiratory syndrome (SARS) coronavirus. This 3'–5" exoribonuclease activity of NP plays critical roles in NP's anti-IFN activity and in other additional steps of mammarenavirus multiplication yet to be elucidated.

Mammarenavirus L proteins have a central region that includes conserved motifs characteristically found in the RdRp domains of negative-sense RNA viruses. Residues critical for LASV L function have been shown to be located both within and outside the predicted RdRp domain. Bioinformatic analysis and structural studies revealed that the N-terminus of LASV L has an endonuclease domain of similar structure to the cap-snatching endonuclease domains of influenza A virus polymerase acidic (PA) and La Crosse virus L proteins. In addition, EM characterization of a functional MACV L has revealed a core ring-domain decorated by appendages, which likely reflects a modular organization of the arenavirus polymerase.

Mammarenavirus Z proteins exhibit a modest degree of overall conservation. However, three regions within Z have a higher degree of conservation: (1) an N-terminal myristoylation site marked by a highly conserved G motif that is critical for membrane anchoring and interaction with other viral proteins; (2) a RING domain that binds two zinc ions through three conserved motifs; and (3) a C-terminal region containing proline-rich motifs that serve as functional late budding motifs. Structural studies revealed that the N- and the C-terminal arms flanking the RING domain are disordered, which may enable Z to recruit a variety of cellular partners to modulate virus multiplication. In addition, Z assembles in a dodecameric manner through a head-to-tail dimerization of the RING domain. These findings are consistent with Z playing a key role in virion assembly, which is further supported by EM

Mammarenavirus Life Cycle

Fig. 2 Mammarenavirus life cycle. Mammarenavirus enter cells via receptor-mediated endocytosis (RME). There are some differences on the specific steps of the pathway used by different mammarenaviruses to reach the late endosome where the acidic environment triggers a pH-dependent fusion event between viral and cell membranes that releases the vRNP into the cytoplasm of the infected cells where viral RNA replication and gene transcription take place. Correct processing of GPC by the cellular signal peptidase and S1P protease is required for the formation of infectious progeny. The matrix Z protein plays critical roles mediating interactions between the vRNP and surface GP complex required for the formation of infectious progeny. Z is also the main driving force of mammarenavirus budding.

studies indicating that Z bridges the viral RNP to the viral envelope proteins. Z is also involved in suppression of the host cell type I IFN response via its interaction with RIG-I-like receptors.

Mammarenavirus Life Cycle

Cell Attachment and Entry

Receptor-mediated endocytosis is the main cell entry pathway used by mammarenaviruses. The acidic environment of the late endosome facilitates a pH-dependent conformational change in the GP complex and subsequent GP2-mediated fusion step between viral and cell membranes. Following fusion, the viral RNP is released into the cytoplasm where it directs both replication and transcription of the viral genome (Fig. 2). The conserved and widely expressed cell-surface receptor for extracellular matrix proteins α -dystroglycan (aDG) is a main receptor for the OW mammarenaviruses LCMV and LASV. Posttranslational glycosylation modification of aDG by the like-acetylglucosaminyltransferase (LARGE) is critical for aDG's function as a mammarenavirus receptor, and specific LARGE alleles have been shown to be positively selected among the Yoruba of Western Africa where LASV is endemic. However, non-pathogenic mammarenaviruses also use aDG-mediated cell entry, indicating that aDG does not play a unique direct role in mammarenavirus pathogenesis. Secondary alternative receptors, including members of the Tyro3/Axl/Mer and T-cell immunoglobulin (TIM) and mucin receptor families may account for LASV and LCMV infection of cells lacking fully glycosylated aDG. Cell entry of the OW hemorrhagic fever (HF) mammarenavirus LUV is mediated by neuropilin (NRP)-2, a cell-surface receptor for semaphorins. NRP-2 is highly expressed in microvascular endothelial cells, which may contribute to LUV-induced coagulopathy. Human transferrin receptor 1 (TfR1) is the main cellular receptor used for cell entry of pathogenic NW mammarenaviruses, including JUNV and MACV. Consistent with the use of TfR1 as a primary receptor, JUNV enters cells through clathrin-mediated endocytosis.

Fig. 3 Mammarenavirus RNA replication and gene transcription. The basic steps of mammarenavirus RNA replication and gene transcription are illustrated for the S segment. Following the pH-dependent fusion event between the viral and cell membranes in the late endosome, the vRNPs are delivered in to the cytoplasm where they initiate transcription from the genome promoter located at the genome 3'-end. Primary transcription results in synthesis of NP and L mRNA from the S and L segments, respectively. Subsequently, the virus polymerase adopts a replicase mode and moves across of the IGR to generate copies of the full length antigenome RNA (agRNA) species that serve as template for the synthesis of the GPC (agS) and Z (agL) mRNAs. The agRNA species serve also as templates for the amplification of the corresponding genome RNA species.

Notably, completion of the cell entry process for LASV and LUJV involves a late endosomal receptor switch mechanism. LASV uses the late endosomal resident proteins LAMP1 and LUJV uses CD36 in these final entry stages.

Expression and Replication of the Viral Genome

NP and L coding regions are transcribed into a genomic complementary mRNA. However, the GPC and Z coding regions are not translated directly from genomic RNA, but rather from genomic sense mRNAs (Fig. 3). These genomic sense mRNAs are transcribed from templates of the corresponding antigenome RNA, which also function as replicative intermediates. Transcription initiation is carried out through a mechanism shared by all negative sense viruses called cap-snatching, in which short fragments of 5'-capped host cell mRNAs are used by virus polymerase complex to prime the synthesis of viral mRNAs. Transcription termination occurs within the distal side of the IGR and generates non-polyadenylated viral mRNAs. Virus replication proceeds in two steps: first, the *de novo* (primer-independent) synthesis of an intermediate RNA with positive polarity (cRNA) and second, using this cRNA as template, the synthesis of progeny genomic vRNA with negative polarity. The 5'-end of arenavirus genome and antigenome RNAs each contain a non-templated G residue that has been proposed to reflect a prime-and-realign mechanism for RNA replication mediated by L.

Using cell-based minigenome (MG) assays, NP and L have been identified as the minimal viral *trans*-acting factors required for efficient RNA synthesis mediated by the virus polymerase. For LCMV, both genetic and biochemical evidence indicate that oligomerization of L is required for polymerase activity. Z is not required for RNA replication and gene transcription mediated by the virus L polymerase, but rather exhibits a dose-dependent inhibitory effect on both RNA biosynthetic processes. Consistent with these findings, studies using in vitro reconstitution of RNA synthesis directed by MACV polymerase have provided evidence that Z, via direct interaction with the polymerase, is able to lock the polymerase in a promoter-bound, catalytically inactive state.

Mutation-function analysis of the genome 5'- and 3'-termini using cell-based MG assays for LCMV, LASV, and MACV indicate that the activity of the arenavirus genomic promoter is dependent on both sequence specificity within the highly conserved 3'-terminal 19 nt of arenavirus genomes and on the integrity of the predicted panhandle structure. This panhandle is formed via sequence complementarity between the 5'- and 3'-termini of viral genome RNAs. Mammarenavirus RNA replication and gene transcription are regulated in a coordinated manner but intracellular levels of NP do not determine the balance between virus RNA replication and transcription. MG-based assays confirmed the IGR role as a *bona fide* transcription termination signal, but synthesis of translation-competent viral mRNAs does not strictly require the presence of the IGR.

Assembly and Budding

Production of infectious mammarenavirus progeny requires both Z and GPC and the correct processing of GPC into GP1 and GP2. Z is a structural component of the virion and cryo-electron microscopy structural studies reveal a location of LCMV Z within virions consistent with its role as a matrix protein. Consistent with its matrix protein function, Z is the main driving force of mammarenavirus budding, a process mediated by the interaction of Z's late domain budding motifs, PTAP or PPPY, or both, with components of the endosomal sorting complexes required for transport (ESCRT) within the vacuolar protein sorting (Vps) pathway. Myristoylation of Z is strictly required for its targeting to the plasma membrane, the location of arenavirus budding (Fig. 2).

Epidemiology of Human Pathogenic Mammarenaviruses

Typically, mammarenaviruses cause persistent, frequently asymptomatic infections in their reservoir hosts, which are characterized by virus multiplication in many different tissues and chronic viremia and viruria. Both, vertical transmission (exposure to infectious virus early in ontogeny) and horizontal transmission (exposure to virus later in life through aggressive or venereal behavior) may contribute to the mammarenavirus chronic carrier state in rodents. Human infections occur via exposure to rodent fomites, ingestion of contaminated food, exposure to broken skin or mucous membranes, or by inhalation of aerosolized virions from contaminated material.

Lassa Fever (LF)

LF is caused by LASV, which is endemic in vast areas of western sub-Saharan Africa. Imported cases of LF have been reported in the United States, Canada, the United Kingdom, Japan, Germany, Netherlands, and Israel. The case-fatality rate (CFR) of LF is about 1%–2% in the endemic areas, with estimated 300,000 infections annually. Most LASV infections in Africa are asymptomatic, mild or subclinical, but the CFR in hospitalized confirmed cases of LF can be as high as 69%. The disease is especially severe late in pregnancy with fetal death, miscarriage, or spontaneous abortion occurring in nearly all cases.

The main reservoir host of LASV is the Natal multimammate mouse (*Mastomys natalensis*). Maintenance of LASV in Natal *mastomys* is thought to occur via vertical transmission but recent studies suggest the existence of an additional horizontal transmission mechanism. Other rodents might also serve as LASV hosts or have roles in LASV transmission. Humans become infected with LASV through direct contact with infected rodent tissues, excreta, or blood or via inhalation of aerosolized virus. Infected meat could contribute to virus transmission in populations that include peridomestic rodents as part of their diet. Person-to-person transmission of LASV can occur in nosocomial settings via direct contact with body fluids from symptomatically infected individuals or corpses. Human infections tend to be more common in the dry season, which may reflect a higher prevalence of Natal *mastomys* within human dwellings. LASV prevalence is focal and varies greatly between geographical regions. For example, in Sierra Leone, seroprevalence ranges from 8% to 52% and in Nigeria from 13% to 37%.

LASV exhibits a high degree of genetic diversity; nucleotide differences can reach up to 32% for the L segment and 25% for the S segments. The genetic diversity among LASV strains correlates with geographic distribution rather than time. This high genetic diversity of LASV might explain the observed variability of LF's clinical presentation and possible regional differences associated with CFRs and disease symptoms.

Lujo Hemorrhagic Fever (LHF)

LHF, caused by LUJV, was identified in 2008 in South Africa. The only known nosocomial outbreak involved five cases of viral HF disease with clinical symptoms remarkably similar to LF, despite LASV and LUJV being distantly related. LHF disease has an abrupt onset and exhibits disseminated intravascular coagulation (DIC), features that distinguish LHF from LF. The overall lack of epidemiological data on the prevalence of LUJV in South Africa and the limited number of verified cases prevents any conclusion on whether the high (80%) CFR associated with the LHF outbreak reflects a more severe disease compared to LF. The natural reservoir of LUJV remains unknown.

Lymphocytic Choriomeningitis (LCM)

The primary host of LCMV is the house mouse. Other rodents, including pet hamsters and domesticated guinea pigs can become infected and transmit the virus to humans. LCMV is transferred vertically from one generation to the next and chronically infected

rodents shed the virus in their urine, saliva, nasal secretions, and droppings throughout life. Mounting evidence indicates that LCMV is a neglected human pathogen of clinical relevance as an under-recognized cause of neurologic disease in the fetus, and adult, and important threat to immune compromised individuals. Humans become infected with LCMV through close contact with infected rodents, solid organ transplantation, or by vertical transmission associated with congenital infections. The seroprevalence of LCMV within house mouse populations and in humans is highly variable, even within the same geographic region, resulting in the focal and uneven spatial distribution of the virus. As with LASV, LCMV exhibits high genetic diversity. Up to 18% and 25% nucleotide divergence was observed within the S and L segments, respectively, of LCMV lineages. The high genetic diversity of LCMV and the lack of clear correlation of virus genetic lineages to particular geographic locations likely reflect the long and complex phylogeographic history of the common house mouse host.

Argentinian Hemorrhagic Fever (AHF)

Junín virus (JUNV), the etiologic agent of AHF, is endemic to the Pampas in Argentina. In the absence of treatment, the CFR rate can reach 20%–30%. Pregnant women have higher CFR and many miscarry, especially if infection occurs during the third trimester. AHF is typically a seasonal disease, with a peak of frequency occurring during the corn-harvesting season, and infected cases are primarily rural male agricultural workers. The drylands laucha (*Calomys musculinus*) is the main reservoir of JUNV but other animals can also become infected. The patchy spatial distribution of the drylands laucha has been suggested to account for the focal distribution of AHF. Annual increase in the number of these rodents coincides with the corn harvesting season providing opportunities for rodent-to-man transmission. Human transmission is thought to occur predominantly by inhaling aerosolized viral particles from contaminated soil and plant litter, which are disturbed during the mechanized harvesting process, or by exposure to primary aerosols of rodent urine or contact with contaminated nesting materials in border habitats. Horizontal transmission via aggressive encounters among adult, male rodents is the primary mode of viral persistence in nature, which is facilitated by the high viral load in saliva of drylands lauchas. Vertical transmission might contribute to the maintenance of JUNV via intra-generational infection by horizontal transmission when population numbers are reduced. Seroprevalence in humans range from 4.7% to 12.3% in AHF-endemic areas, and significantly lower (0.44%) in non-endemic areas. In rodents, prevalence of infection can be as high as 10.9% with highest prevalence observed in current epidemic areas and lowest (0.2%) in non-endemic areas. In contrast to LASV and LCMV, Nucleotide similarity between JUNV strains is high, reaching up to 94.5% and 95.4% for GP and NP, respectively.

Bolivian Hemorrhagic Fever (BHF)

The CFR of BHF, caused by Machupo virus (MACV), is approximately 5%–30% with the highest rates occurring among those under 5 and over 55 years of age. BHF cases are more common at the peak of agricultural activity, during the dry season, with males over 15 years of age more frequently affected. The big laucha (*Calomys callosus*) is the reservoir host of MACV. Both horizontal and vertical transmission have been shown as possible maintenance mechanism of MACV within its reservoir rodent. Person-to-person transmission of MACV is possible but rather uncommon, likely reflecting the infrequent and low virus detection in blood or from throat and oral swabs of infected patients.

Venezuelan Hemorrhagic Fever (VeHF)

Guanarito virus or GTOV emerged in 1989 as the cause of VeHF, a severe hemorrhagic illness with CFR of $\approx 30\%$. The disease has focal distribution in the southern and southwestern portions of Portuguesa state and in adjacent areas of Barinas state. VeHF cases peak during the period of agricultural activity in these regions and involve mainly male agricultural workers. The short-tailed zygodont (*Zygodontomys brevicauda*) is the main reservoir host of GTOV. The virus is also commonly found in Alston's cotton rats (*Sigmodon alstoni*). These hosts have not been reported within houses or farm building. Therefore, infections are assumed to occur outdoors, in rural areas, and persons that have frequent contact with rodent-infested grassland habitats are at higher risk.

Pathogenesis and Pathology

The mechanisms underlying pathogenesis of mammarenaviral disease in humans are not well understood. Pathological findings in patients' autopsies do not account for the severity of symptoms seen in many cases of human mammarenaviral disease. Mammarenaviruses typically enter humans in an aerosolized form and are deposited in the lung, where initial viral replication occurs. Antigen-presenting cells (APCs), DCs and macrophages, are prominent targets in the initial stages of infection, and facilitate virus access to the lymphoid system and subsequent systematic spread to other organs and tissues including liver, kidneys, lungs, adrenal glands, and heart. LASV has also been recovered from placenta, mammary glands, and aborted fetal tissues, and in cases of AHF, virion-like particles were detected in the central nervous system (CNS), ovaries, and testes. LCMV load can reach high levels in meninges, choroid plexus, and ventricular ependymal linings, where the inflammatory response produces the characteristic LCM pathology. LCMV exhibits a strong tropism for the fetal brain, where LCMV congenital infection produces its

most common and severe pathologic effects, including microencephaly, periventricular calcifications, hydrocephalus, cerebellar hypoplasia, focal cerebral destruction, and gyral dysplasia.

The extent of hemorrhagic and coagulopathy manifestations differs between human pathogenic mammarenaviruses. Hemorrhages are common in AHF cases, but are rare and mainly limited to mucosal surfaces in LF cases. Bleeding is usually associated with thrombocytopenia and platelet dysfunction. Fatal cases of LF are associated with lower levels of platelet activating factor (PAF) and PAF-like molecules, as well as hemoglobin breakdown products D-urobilinogen and I-urobilin. Disseminated intravascular coagulation (DIC) or complement activation do not appear to play a role in mammarenavirus pathogenesis.

Impaired vascular endothelium function, including increased permeability, likely plays a central role in LF and AHF pathogenesis. However, only minimal vascular histological lesions are detected in fatal human LF and AHF cases and infected non-human primates (NHPs), and the mechanisms responsible for virus induced increase in vascular permeability remain to be elucidated. In contrast to other HF-causing viruses, LASV and JUNV do not trigger a “cytokine storm” that could interfere with the integrity of the vascular endothelium, but infection of the endothelium might cause changes in endothelial cellular function leading to increased fluid flow and subsequent edema.

Pathological findings in LF patients include both macroscopic and microscopic abnormalities. Gastric mucosal, renal, and subconjunctival hemorrhages, petechiae, and increased vascular permeability are common macroscopic observations, whereas microscopic observations include multifocal hepatocellular necrosis with modest inflammatory cell involvement, splenic necrosis, necrosis of renal tubular cells, adrenocortical cell necrosis, focal renal interstitial lymphocytic infiltrates, mild mononuclear interstitial myocarditis, alveolar edema with capillary congestion, interstitial pneumonitis, and rhabdomyositis.

The most consistent pathological hallmark of LF in humans is multifocal hepatocellular necrosis. High virus titers in liver tissue correlate with severe hepatitis. However, the degree of hepatic tissue damage is insufficient to cause hepatic failure, and there is no correlation between the degree of hepatic necrosis and chemical indicators of liver damage, indicating that LASV-induced hepatitis is unlikely to be the primary cause of death in fatal cases of LF.

The most common macroscopic abnormality observed in severe cases of NW mammarenaviral disease is widespread hemorrhage affecting the skin and mucous membranes, Virchow-Robin space, kidneys, pericardium, spleen, adrenal glands, and lungs. Microscopic lesions include acidophilic bodies, focal liver necrosis, acute tubular and papillary necrosis in the kidneys, and reticular hyperplasia of the spleen and lymph nodes. Pathognomonic symptoms of AHF illness can vary depending on the specific JUNV strain and can be “hemorrhagic”, “neurologic”, “mixed”, and “common”. Infection with “hemorrhagic” strains results in a pronounced bleeding tendency with disseminated cutaneous and mucous membrane hemorrhage. In contrast, infection with “neurologic” strains show little or no hemorrhagic manifestations but result in overt and progressive signs of neurologic dysfunction.

LCM disease correlates with detection of viral antigen in meninges and cortical neurons, as well as mononuclear cell infiltrates in the meninges and around vessels and glial nodules in the deeper structures, suggesting an immune-mediated pathology associated with LCMV infection. An animal model of congenital LCMV infection revealed a very strong tropism of LCMV for neuroblasts and altered neuron migration, findings that may explain the location of periventricular calcifications and the gyral malformations in children with congenital LCMV.

Clinical Features

LF and LHF

LF is mild or asymptomatic in about 80% of infected individuals, but 20% develop acute LF. The incubation period can range from 5 to 21 days but is typically 10–14 days. Within 2–4 days of infection, many patients experience an array of symptoms including headache, myalgia, arthralgia, lower back, abdominal and retrosternal chest pain, dizziness, nausea, tinnitus and sore throat. Cough, vomiting, diarrhea and constipation are also common, whereas lymphadenopathy, oliguria, tachycardia, vertigo, splenomegaly, hepatomegaly, and jaundice have been reported occasionally. Disease progression is often associated with pharyngitis, conjunctivitis, respiratory distress, pleural and pericardial effusions, and facial and neck edema. In most cases of LF recovery begins 8–10 days after disease onset, and 4–11 days later viremia is undetectable. In contrast, in severe cases of LF, worsening of symptoms and hemorrhagic and neurologic manifestations are more common. Hemorrhagic manifestations can affect skin and mucosal surfaces. Neuroglial findings including diffuse encephalopathy, confusion, tremors, coma, and convulsions are common prior to shock and death. Widespread edema can be observed in children with LF, which usually has a fatal outcome.

Common clinical findings in LF cases include proteinuria, albuminuria, and elevated AST levels, whereas moderate leukopenia has been reported only in some patients. Survivors of LF often recover without sequelae. However, long-term unilateral or bilateral sensorineural deafness can affect a significant ($\approx 13\%$ – 30%) number of survivors.

Known cases of LHF disease presented with similar clinical symptoms to those documented for LF cases. Initial symptoms of nonspecific febrile illness increase in severity over 7 days with the development of diarrhea, pharyngitis, and facial and neck edema. Terminal features are shock and multi-organ system failure often with evidence of DIC that resulted in death of four of the five LHF cases.

LCM

In most healthy individuals, LCMV infection course is asymptomatic, or manifested as a mild febrile illness. Following 1–2 weeks of incubation, some infected individuals may develop a flu-like illness that could include anorexia and gastrointestinal

symptoms. Sore throat, cough, pharyngitis, and other symptoms of respiratory tract involvement are less common. Leukopenia, moderate thrombocytopenia, mild elevations of AST, and infiltrates on chest radiographs can be seen in some patients. Additional, but rather infrequent, reported clinical findings are lymphadenopathy, dysesthesia, conjunctivitis, arthralgia, arthritis, rash, testicular or parotid pain, as well as abdominal, back, and chest pain. LCMV invasion of the CNS can occur in some infected individuals, usually resulting in symptoms of classic aseptic meningitis. In some cases, encephalitis, encephalomyelitis, meningoencephalitis, acute hydrocephalus, ascending or bulbar paralysis, or transverse myelitis may develop. CSF pleocytosis is characteristically observed during this CNS phase of illness and LCMV can be isolated from the spinal fluid. Infections are rarely fatal, and most patients recover without sequelae, but some might experience asthenia, headaches, confusion and difficulty in concentration.

LCMV Infection during pregnancy, especially during the first trimester, increases the risk for miscarriage, *in utero* fetal death, fetopathy, and severe neurologic sequelae. Congenital LCMV can result in severe CNS or ocular malformations and can mimic the signs/symptoms of classic TORCH syndrome. In immunosuppressed organ recipients, LCMV infection can be fatal due to multi-organ system failure with LCMV-associated hepatitis as a prominent feature. In most immunosuppressed patients CNS manifestations are also observed. Clinical findings in these patients include elevated transaminases levels, leukopenia, and thrombocytopenia, as well as increased protein levels and leukocyte numbers in CSF.

NW Mammarenaviral HFs

AHF has an incubation period of 1–2 weeks, followed by a prodromal phase characterized by fever and malaise, headache, myalgia, epigastric pain, and anorexia. After 2–4 days, signs become increasingly severe including prostration and GI disturbances. In some cases, dizziness, photophobia, retro-orbital pain, or disorientation may also occur. Initial signs of vascular damage may appear at this early phase of AHF. During the second week of illness, about 20%–30% of patients develop severe hemorrhagic and neurologic manifestations, or secondary bacterial infections. Hemorrhagic manifestations include bleeding from mucous membranes and ecchymosis at needle puncture sites, but only very modest blood loss is observed. Neurologic manifestations include seizures, convulsions, tremor of the hands and tongue, and less frequently, delirium, coma, encephalitis and meningoencephalitis. Following shock, death usually occurs 7–12 days after disease onset. Clinical laboratory findings include leukopenia and thrombocytopenia and non-specific electrocardiogram abnormalities, whereas chest radiography is usually normal in the absence of secondary infections. Patients' clinical improvement during the second week of AHF correlates with the appearance of neutralizing antibodies. Convalescence often lasts several weeks with polyuria, fatigue, alopecia, and dizziness.

BHF and VeHF caused by MACV and GTOV, respectively, as well as NW mammarenaviral HF caused by CHAPV and SBAV, display clinical symptoms similar to those described for AHF. Proteinuria and elevated hematocrit during the peak of hemorrhagic manifestations are characteristic of severe cases of BHF. Early symptoms of VeHF disease are indistinguishable from dengue fever, also common in Venezuela. CNS manifestations of VeHF including encephalitis are associated with poor prognosis. Hearing loss has been reported in convalescence cases of VeHF. The only reported case of a naturally acquired infection with SBAV caused disease with symptoms similar to those of other NW mammarenaviral HF, but also included extensive liver necrosis.

Diagnosis

LF

LASV can be isolated from blood during the febrile phase of LF disease, as well as from autopsy tissue samples. Serum detection of LASV antigen by ELISA is robust, reliable, and can be completed in a short time. LASV-specific antibodies can be detected by immunofluorescence (IF) and ELISA. ELISA IgM titers appear earlier and persist longer than IF IgM titers. Virus-specific IgG ELISA antibody detection persists for long periods, whereas IF antibody appears to wane over time below detectable limits. Reverse transcriptase-PCR (RT-PCR) can detect virus RNA in blood with high sensitivity. Nanopore sequencing using the MiniON device was successfully used to genetically characterize LASV isolates during the 2018 upsurge of LF cases in Nigeria. The ability of this portable sequencing technology to genetically characterize *in situ* RNA viral samples in real-time cases of LASV infection associated with disease symptoms will represent a major breakthrough in the study of LF epidemiology.

LF presents with symptoms indistinguishable from those of other febrile illnesses including malaria, and therefore it is difficult to diagnose LF clinically, but it should be suspected in patients with fever ($\geq 38^{\circ}\text{C}$) not responding to antimalarial and antibiotic drugs. Useful clinical findings for diagnosis of LF are fever, pharyngitis, retrosternal pain, and proteinuria. Viremia levels, fever, sore throat, vomiting, edema, and bleeding are the predictors of poor prognosis. CNS signs, face and neck edema, jaundice, bleeding, hematuria, and proteinuria were shown to be associated with a fatal outcome. Several biomarkers including increased levels of blood urea nitrogen and creatinine (biomarkers for kidney function), serum AST (liver malfunction), and serum electrolyte potassium, have been shown to have a strong correlation with CFR, highlighting the role of liver and renal dysfunction and electrolyte disturbance in the severity of LF.

LCM

LCMV can be isolated from blood during the febrile phase of LCM and during meningitis symptoms, but CSF contains higher viral load, and PCR-based tests using CSF samples have been successfully used. LCMV-specific IgM antibodies can be detected by ELISA and IF in serum and CSF in acute cases of LCM. Neutralizing antibodies appear late after onset of disease and their diagnostic value is limited.

NW Mammarenaviral HF

During the acute febrile phase of disease, virus can be isolated from blood samples by inoculation of newborn hamsters or mice, but cocultivation of patient's peripheral blood mononuclear cells with Vero cells may offer higher level of sensitivity. Virus can also be isolated from autopsy tissues, with the exception of brain. Viral antigen in blood and tissues from patients with JUNV, MACV, SBAV, or GTOV infection can be usually detected by antigen-capture ELISA. Serologic diagnosis of AHF and BHF is usually made by IF and CF, but the limited specificity and sensitivity of these tests pose problems. The ELISA test is the most useful and practical for rapid detection of IgM and IgG antibodies in a clinical setting and sero-epidemiologic surveys. The plaque neutralization test can be valuable for evaluation of convalescent plasma units intended for therapeutic use in AHF.

Prevention and Control

Medical Management

Supportive therapy including hydration and pain relief management represent standard of care in suspected cases of mammarenaviral HF. Platelet transfusions and factor replacement could help to control bleeding. Infusion of crystalloids to counteract the commonly observed moderate degree of vascular permeability should be carefully considered due to a high risk of pulmonary edema. The low cardiac output observed in human cases of AHF support the use of Swan-Ganz catheterization. LCMV ependymal infection and inflammation may cause acute hydrocephalus and a need for surgical shunting. Management of patients that undergo shock is difficult.

Patients with mammarenaviral HF pose in general a low risk of contagion. However, nosocomial outbreaks and infection of multiple contacts have occurred when the index case was severely ill with high viremia and viral load in tissues. Patients may excrete virus in urine or semen for weeks after recovery from disease. Therefore, body fluids should be monitored for infectivity before the patient is released, and counseling should be provided emphasizing protection of sexual partners and the use of disinfectant prior to use of toilets. The highest exposure risk is parenteral and can be minimized through staff training. Respiratory protection against small-particle aerosols should be implemented with caregivers and people in close proximity to patients. Special precautions are indicated when blood and other body fluids are handled in the clinical laboratory.

Antiviral Drugs

The prophylactic and therapeutic value of the nucleoside analog ribavirin (Rib) against human pathogenic mammarenaviruses is well supported by results from both cell culture and animal models of infection. Importantly, Rib reduced both morbidity and mortality in human cases of LF, and evidence suggests that Rib treatment can have also clinical benefits in cases of JUNV, MACV and SABV infections. However, the need of intravenous administration for optimal efficacy, poor penetration into the CSF, and side effects, including anemia and congenital disorders, pose some limitations to the use of Rib. In addition to Rib, several compounds have been reported to have anti-mammarenaviral activity in cultured cells, but their safety and efficacy *in vivo* remain to be determined. The broad-spectrum antiviral favipiravir and the mammarenaviral GP-mediated fusion inhibitor ST-193 have yielded very promising results in different animal models of mammarenaviral disease.

Progress in mammarenavirus molecular genetics has facilitated the development of screens to identify drugs targeting specific steps of the arenavirus lifecycle. These drugs include direct-acting antivirals (DAAs) that target specific viral gene products and functions, and drugs that target host-cell factors (HTAs) required for the completion of virus replication cycle. Combination therapy of DAAs and HTAs should counteract the emergence of drug resistant variants often observed with monotherapy strategies. Moreover, related viruses are likely to rely on the same host machinery, thus providing an opportunity for the development of broad-spectrum antiviral therapeutics.

Limited market opportunities are an obstacle for the development and licensing of new antiviral drugs against human pathogenic mammarenaviruses. It would be therefore beneficial to use the newly developed screening platforms to implement drug repurposing strategies that can significantly reduce the time and resources required to advance a candidate antiviral drug into the clinic. Moreover, drug repurposing can generate new knowledge on virus biology by uncovering previously unexplored pathways and specific host cell factors contributing to virus multiplication, knowledge that can be harnessed to identify new targets and therapeutics.

Antibody Therapy

Treatment of AHF cases with convalescent plasma from survivors of AHF has been shown to be quite effective in reducing AHF-associated mortality. About 10% of patients treated with convalescent plasma may exhibit usually self-limited neurologic signs including fever,

headache, cerebellar tremor, and cranial nerve palsies, which may reflect the prior invasion of the CNS by the virus. Studies in animal models of infection suggest that passive antibody therapy could be also helpful to treat BHF, VeHF and LF. Experimental studies of passive protection by monoclonal antibodies have been successful in LCMV. Notably, LASV GPC-specific recombinant human monoclonal antibodies derived from survivors of LF with strong neutralization profiles in cell-based assays have shown robust therapeutic efficacy in guinea pig and non-human primate (NHP) models of LF, supporting the feasibility of antibody-based therapy against LF.

Vaccines

The safety, immunogenicity, and protective efficacy of the JUNV live-attenuated Candid #1 strain was demonstrated in preclinical studies in both guinea pig and NHP models of AHF. Vaccination campaigns focused on agricultural workers in the JUNV-endemic area showed Candid #1 to be an effective and safe vaccine in humans, and it was licensed in 2006 for use exclusively in Argentina. However, comparison of Candid#1 clonal isolates from blood of vaccinated NHPs revealed a 1000-fold range of virulence among them, raising some concerns about the stability of the Candid #1 vaccine.

LASV is the mammarenavirus that poses the highest concern to human health due to morbidity and lethality associated with LF together with the vast LASV-endemic regions and size of the population at risk in Western Africa. Accordingly, LF has been included on the revised list of priority diseases of the WHO R&D Blueprint for which the development of a vaccine is encouraged. Studies involving LF survivors and animal models of LASV infection indicate that early and robust virus-specific CD4⁺ and CD8⁺ T cell responses, rather than the presence of neutralizing antibodies, which appear late after infection and at low titers, are the best correlates of recovery and protection. Although antibodies do not appear to contribute to viral control and recovery during acute LASV infection, genetically engineered neutralizing monoclonal antibodies can be successfully used for immunotherapy. These data suggest that an ideal LASV vaccine should trigger both long-term robust cell-mediated immunity (CMI) and humoral responses following a single immunization, features frequently displayed by live-attenuated vaccines (LAV). A number of LASV vaccine platforms have shown promising result in animal models of LASV, including LAV candidates based on vaccinia virus, vesicular stomatitis Indiana virus (VSIV), Mopeia virus (MOPV) an OW arenavirus closely related to LASV, yellow fever virus 17D vaccine strain, measles virus (MV)-based vector, alphavirus replicons and the ML29 reassortant carrying the L segment of the non-pathogenic MOPV and the S segment of LASV.

The Coalition for Epidemic Preparedness Innovations (CEPI) was created as non-profit organization to accelerate vaccine development against emerging epidemic infections for which the commercial market is insufficient to justify private investment. LASV vaccine candidates supported by CEPI include recombinant VSV and MV expressing LASV GPC and DNA-based vaccines. A single injection of rVSV/LASV-GPC experimental vaccine, in which VSIV G was replaced with LASV GPC, fully protected guinea pigs and NHPs against LASV strains from the same clade. Despite these promising results, there are still some safety concerns because of reported side effects in individuals vaccinated with an Ebola virus vaccine based on the same platform (rVSVΔG/EBOV-GP), which included post-vaccination arthritis, vector RNAemia, and detection of infectious vaccine virus in the skin of vaccinated individuals. The MV-based vector vaccine platform has shown promising results in human clinical trials providing antibody-based protection. Whether this platform would be effective for development of a vaccine against LASV with predominant T cell-mediated mechanism of protection remains to be determined. Currently there is no human licensed preventive DNA vaccine for any infectious disease, which poses great technical obstacles for developing an DNA-based vaccine against LASV.

The LASV candidate vaccine reassortant ML29 induced a robust cross-reacting and protective, sterilizing cell-mediated immune response against strains from distantly-related LASV lineages in a guinea pig model of LF. In addition, ML29 was shown to be stable and safe in animal models of LF, including immunocompromised NHPs. This finding is relevant because the LASV vaccine target population will likely include individuals with some degree of undiagnosed immune suppression due to the high prevalence of malaria and HIV-1 infections in Western Africa. Progress in arenavirus molecular genetics can also facilitate the implementation of novel strategies for the development of safe and effective LF vaccines based on the use of codon deoptimization and reorganization of the coding and non-coding intergenic regions.

Perspective

Since the discovery of LCMV more than 70 years ago, mammarenaviruses have served as important model systems for the study of host-virus interactions. Specifically, studies with LCMV in mice, the virus's natural reservoir, have uncovered a wide range of principles in the fields of virology and immunology that apply universally to other viral infections, including virus-induced immunopathology, MHC restriction, the contribution of negative immune regulators to viral persistence, and the concept of T cell exhaustion and demonstration that PD-1/PD-L1 blockade can rescue T cell function. In addition to their impact on basic science, mammarenaviruses include several human pathogens that remain a significant public health risk in much of the world. Control of human pathogenic mammarenaviruses faces significant obstacles including current limited diagnostic protocols and sparse resource allocation for vaccine development and other medical countermeasures. However, progress in molecular genetics has facilitated novel approaches for the investigation of mammarenavirus molecular and cell biology, whereas the application of next generation sequencing technologies has brought a major breakthrough to the investigation of mammarenavirus epidemiology including their prevalence and distribution, as well as genetic diversity. This new knowledge has had also great implications for the development of new approaches to antivirals and vaccines to combat human pathogenic mammarenaviruses.

Nomenclature

BKPyV	BK polyomavirus	NCCR	Non-coding control region
HIV	Human immunodeficiency virus	NJPyV	New Jersey polyomavirus
HPyV	Human polyomavirus	PML	Progressive multifocal leukoencephalopathy
JCPyV	JC polyomavirus	PyV	Polyomavirus
KIPyV	KI polyomavirus	PyVAN	Polyomavirus-associated nephropathy
LIPyV	Lyon IARC polyomavirus	STAg	Small T (tumor) antigen
LTAg	Large T (tumor) antigen	STLPyV	St. Louis polyomavirus
MCC	Merkel cell carcinoma	TSPyV	Trichodysplasia-spinulosa polyomavirus
MCPyV	Merkel cell polyomavirus	VP	Viral protein
MWPyV	Malawi polyomavirus	WHO	World Health Organization
		WUPyV	Washington University polyomavirus

Glossary

IHC Immunohistochemistry, an experimental method used in diagnosis to test for the presence of antigens, such as viral antigens, in a tissue section through the use of antigen-reactive antibodies.

Receptor A molecule that is expressed in the cell membrane and serves as an attachment site for a ligand such as a virus.

Seroprevalence The frequency of positive occurrence of a particular disease or condition (viral infection) within a population as measured by serological (blood) tests.

Tissue tropism Specific cells and tissues that are able to support the replication of a particular virus.

Introduction

Human polyomaviruses (HPyVs) commonly infect the majority of the population, and serological studies suggest that transmission occurs during childhood but seroprevalence continues to increase into adulthood. Transmission of HPyVs is thought to occur via direct person-to-person contact, contact with fomites, or through the ingestion of contaminated food or water. HPyVs demonstrate a high degree of species-specificity, and thus tractable animal models for studies of HPyVs are lacking, and the majority of the clinical data is from observations of human subjects. In addition, this group of viruses exhibits a narrow tissue tropism, generally targeting specific tissues within the host. HPyVs establish life-long persistent infections in target host cells resulting in asymptomatic infections. However, under conditions of immunosuppression such as HIV infection or use of immunosuppressive agents for immune-mediated diseases, HPyVs can become reactivated and cause a range of serious clinical diseases.

BK and JC polyomaviruses were first identified in the 1970s after isolation from patients with nephropathy and progressive multifocal leukoencephalopathy (PML), respectively, and are named after the patients. Another human polyomavirus was not identified until the 2000s, and since that time, there have been 11 newly-identified human polyomaviruses isolated from various tissues and fluids including respiratory samples, urine, stool, blood, skin, and liver ([Table 1](#)). The increase in HPyV isolation and identification was ignited by improved technologies such as rolling circle amplification (RCA) and high-throughput viral sequencing. Karolinska Institute polyomavirus (KIPyV) and Washington University polyomavirus (WUPyV) were both isolated from nasopharyngeal tissue and named for the research institute credited with the identification. Merkel cell polyomavirus (MCPyV) was isolated from individuals with Merkel cell carcinoma (MCC) and was identified as a causative agent of MCC. Shortly thereafter, HPyV6 and HPyV7 were identified from normal skin tissues, although they are now linked to pathologies of the skin including dermatoses. The eighth polyomavirus identified was Trichodysplasia Spinulosa-associated polyomavirus (TSPyV) named for the TS skin lesions from which it was isolated. HPyV9 was isolated from blood, skin, and urine of a kidney transplant recipient, and HPyV10 or Malawi (MWPyV) was isolated from stool samples and from condylomas from a patient with warts, hypogammaglobulinaemia, infections, and myelokathexis (WHIM) syndrome. St. Louis polyomavirus (STLPyV)/(HPyV11) was identified in stool samples from children in Malawi, The Gambia and St. Louis. HPyV12 was isolated from human liver tissue and stool, and New Jersey polyomavirus (NJPyV)/(HPyV13) was isolated from a muscle biopsy and skin lesions in a pancreas transplant recipient with vasculitis and necrotic plaques. The most recently identified polyomavirus, Lyon IARC polyomavirus

Table 1 Human polyomaviruses and associated diseases

Number Designation	Polyomavirus	Isolation source	Year of Disease association ID
HPyV1	BK polyomavirus (BKPyV)	Urine	1971 Polyomavirus-associated nephropathy, hemorrhagic cystitis
HPyV2	JC polyomavirus (JCPyV)	Brain	1971 Progressive multifocal leukoencephalopathy
HPyV3	Karolinska Institute polyomavirus (KIPyV)	Nasopharyngeal tissue	2007 <i>Potential mild respiratory illness</i>
HPyV4	Washington University polyomavirus (WUPyV)	Nasopharyngeal tissue	2007 <i>Potential mild respiratory illness</i>
HPyV5	Merkel cell polyomavirus (MCPyV)	Tumors, skin	2008 Merkel cell carcinoma
HPyV6	Human polyomavirus 6	Skin	2010 Pruritic and dyskeratotic dermatitis
HPyV7	Human polyomavirus 7	Skin	2010 Pruritic and dyskeratotic dermatitis
HPyV8	Trichodysplasia spinulosa-associated polyomavirus (TSPyV)	Skin lesions	2010 Trichodysplasia spinulosa
HPyV9	Human polyomavirus 9	Blood, skin, urine	2011 ?
HPyV10	Malawi polyomavirus (MWPyV)	Stool, condylomas	2012 ?
HPyV11	St. Louis polyomavirus (STLPyV)	Stool	2012 ?
HPyV12	Human polyomavirus 12	Liver, rectum, stool	2013 ?
HPyV13	New Jersey polyomavirus (NJPyV)	Muscle, skin	2014 ?

(LIPyV), discovered in 2017, was isolated from skin swabs and oral fluids. LIPyV has not yet been formally assigned as a human polyomavirus species, yet it could be the fourteenth HPyV.

HPyVs within the family of *Polyomaviridae* share remarkable similarities in structure and genome composition and organization. In addition to their overall similarities in virion structure and genome organization, there are many parallels in the general schema of the infectious viral cycle including viral attachment, entry, trafficking, and the temporally regulated gene expression. However, the specific cellular factors required for a productive infectious cycle for each virus are disparate. Furthermore, polyomaviruses demonstrate a broad tissue tropism in the human host infecting skin, kidney, and brain cells, yet pathogenic viral disease is generally limited to those with an underlying immunosuppression. Polyomavirus disease ranges from nephritis to a fatal infection of the brain to skin cancer. The commonalities across structure, genome, and life cycles of HPyVs is described herein as well as detailed sections on specific differences in viral life cycles and clinical diseases of select HPyVs, including BK polyomavirus (BKPyV), JC polyomavirus (JCPyV), Merkel cell polyomavirus (MCPyV), and other recently-discovered HyPVs associated with significant human disease manifestations.

Virion Structure

Human polyomaviruses are classified by a nonenveloped protein capsid that is ~40–45 nm in diameter (Fig. 1). The virion capsid is comprised of two to three structural proteins, viral protein 1 (VP1), VP2, and VP3. VP1 is a pentameric protein that associates with either a VP2 or a VP3 in the interior of the virion capsid (Fig. 1). VP1 is the only capsid protein expressed on the exterior of the surface and serves as the viral attachment protein. Polyomavirus capsids are made up 360 molecules of VP1 arranged into 72 pentamers. The pentameric VP1 proteins associate with neighboring VP1 pentamers via C-terminal extensions in which the 72 pentamers are organized as 60 hexamers and 12 pentamers allowing for the formation of a spherical, capsid with a $T=7d$ skewed icosahedral structure. VP1 pentamers from all human polyomaviruses exhibit a β barrel jelly roll structure of VP1 monomers, formed by anti-parallel β strands, and the connecting loops of which serve as the binding site for many HPyV sialic-acid containing receptors. The virion capsid is stabilized by intra- and inter-pentameric disulfide bonds and calcium ions, and assembly occurs entirely in the nucleus where the concentration of calcium ions is highly regulated. The N-terminal region of the VP1 pentamers faces the interior of the virion and binds the minor capsid proteins, VP2 or VP3, which can interact with genomic DNA (Fig. 1).

Genome

Encased within the virion capsid is the circular double-stranded (ds) DNA genome that is approximately 5000 bp in size and packaged with cellular histones. The simple genome is comprised of 5–6 protein-coding genes resulting in a relatively limited protein repertoire, yet the polyomaviruses genome structure and organization are fairly conserved among HPyVs (Fig. 2). Polyomavirus genomes are divided into three regions organized in a bidirectional manner into early and late regions separated by a non-coding control region (NCCR) or regulatory region (RR). The early region of the genome encodes for the early viral proteins, the nonstructural proteins large T antigen (LTAg), small t antigen (STAg), and in some cases middle t antigen (MT), alternative T (ALT), and alternatively spliced T' proteins are encoded from an alternative splicing of a single mRNA transcript. The late viral

Fig. 1 Icosahedral structure of nonenveloped human polyomavirus virion. (A) High resolution structure of BKPyV resolved by cryo-electron microscopy (EM) at 3.8 Å demonstrating. (B) A view of the BKPyV virion interior with VP1 pentons (gray), VP2 (blue), and VP3 (green) and packaged dsDNA (yellow, pink). (C) Enlargement from structure (in (B)) demonstrates VP2/VP3 interactions with dsDNA, which is wrapped in cellular histones. Modified and reproduced from Hurdiss *et al.*, 2018. Structure. 26 (5), 839–847. and Hurdiss *et al.*, 2016. Structure. 24 (4), 528–536. under Creative Commons licenses.

Fig. 2 General schematic of human polyomavirus genome. The dsDNA genome size is ~5000 bp and is organized into early and late regions separated by the non-coding control region (NCCR). The NCCR contains the origin of replication (ORI), and replication is driven through several functions of TAg, including helicase activity to unwind the viral dsDNA genome. The early region encodes for T antigen proteins including large T antigen (LTAg), small T antigen (STAg), and other splice variants of T antigen (indicated by dashed line, varies by HPyV). Not pictured are middle T Ag and truncated T Ag, present in some HPyVs. The late region encodes for structural proteins viral protein 1 (VP1), VP2, and VP3 (lacking in MCPyV). Some HPyVs, including JCPyV and BKPyV also encode for the nonstructural protein agnoprotein. Figure artwork generated by Michael Wilczek.

genes include the viral structural proteins VP1, VP2, and VP3 (except for MCPyV). JCPyV and BKPyV encode for an additional protein, agnoprotein, which is expressed predominantly in the cytoplasm of infected cells and is required for release of infectious progeny into the supernatant. JCPyV Agno protein has been demonstrated to play a role in egress through the nuclear membrane. The NCCR demonstrates genomic diversity among polyomaviruses and contains promoters for early and late genes, the origin of replication (ORI), a binding domain for LTAg, and promoters and enhancers. HPyV NCCRs undergo rearrangements within the host during active viral replication, yielding insertions, deletions, and duplications. The rearranged NCCR of polyomaviruses are generally associated with enhanced viral replication, expansion of tissue tropism, and thus viral pathogenesis. Viral strains with rearranged NCCRs are generally only found during viremia or pathogenic states. A number of HPyVs, including BKPyV, JCPyV, and MCPyV have been demonstrated to also encode for microRNAs (miRNAs) complementary to LTAg. These miRNAs can function by binding to LTAg mRNA and regulating expression of early genes and contribute to viral immune evasion.

Fig. 3 General schematic of human polyomavirus life cycle. (1) Viral attachment is mediated by VP1 binding to sialic-acid containing receptors or alternate receptors such as glycosaminoglycans or serotonin receptor. (2) Viral entry is mediated via endocytosis (mechanism varies by HPyV). (3) HPyVs traffic through the endocytic compartment to the endoplasmic reticulum (ER), and (4) the virions are partially disassembled in the ER. (5) Transcription begins with viral early genes followed by replication of the dsDNA genome then transcription of viral late genes. (6) Virions are assembled in the nucleus before (7). release, possibly through cell lysis. Figure generated by Jeanne DuShane and created in [BioRender.com](#).

Infectious Cycle

Despite differences in tissue tropism and broad effects on host cells, the current information for human polyomaviruses suggests they follow the same general schema for infection of host cells ([Fig. 3](#)). HPyVs bind to cell surface receptors on host cells, and for most HPyVs this has been demonstrated to be a carbohydrate sialic acid receptor. The nature of the carbohydrate receptor differs among polyomaviruses but can include $\alpha 2,3$ -, $\alpha 2,6$ -, or $\alpha 2,8$ -linked sialic acids or alternate receptor such as glycosaminoglycans. In fact, a number of HPyVs attach to a sialic acid receptor expressed on a ganglioside, a glycosphingolipid comprised of a ceramide in a lipid-rich region of the membrane with an extracellular carbohydrate moiety with sialic acid residues. The utilization of gangliosides results in a lipid-mediated caveola- or lipid raft-mediated internalization process for some HPyVs. However, JCPyV requires a unique sialic acid receptor $\alpha 2,6$ -linked lactoseries tetrasaccharide c (LSTc) and also requires a secondary receptor, the 5-hydroxytryptamine family of receptors (5-HT) in the 2 subfamily and clathrin-mediated endocytosis viral internalization. BKPyV has also been demonstrated to enter specific cell types via a caveolae- and clathrin-independent mechanism.

Regardless of the internalization strategy, polyomaviruses are internalized into the endocytic compartment and traffic to the endoplasmic reticulum (ER). Within the ER, resident chaperones, disulfide isomerases and reductases, and components of the ER-associated protein degradation (ERAD) pathway facilitate partial uncoating of the viral capsid. The partially disassembled virion is then deposited into the cytoplasm and retrotranslocates to the nucleus where transcription and replication ensues in a temporally-regulated process. Transcription of viral early genes is initiated through host cell RNA polymerase II and transcription factors binding to the promoter region of early genes. A precursor mRNA is generated, which is then alternatively spliced to produce large tumor (T) antigen (LTag), small T antigen (STAg) and TAg splice variants. LTag is considered a master regulator of polyomavirus infection, exerting multiple functions necessary for the infectious process. The expression of LTag and STAg drives cell cycle progression from G0 or G1 into S phase by binding to cell cycle regulators pRb, p53, and PP2A. LTag binds pRb family members through the conserved LXCXE motif. Some HPyVs have additional open reading frames (ORFs) that encode for proteins although their functions are not well described. TSPyV and MCPyV encode for additional T antigens, middle T antigen (MTAg) and alternative tumor antigen (ALT), respectively. While the function of MTAg and ALT are not yet well characterized, they are expected to play roles in cellular proliferation and transformation due the presence of Rb binding motifs. Viral replication is carried out through reliance on the cellular replication machinery and proceeds in a bidirectional manner. LTag binds to the ori in the NCCR, unwinds the dsDNA genome through helicase activity, and drives viral replication. Finally, late viral gene transcription ensues on the complementary strand in the opposing direction from the early genes to produce the late viral genes VP1, VP2, and, in most cases, VP3, which then encapsidate the virion in the nucleus. MCPyV lacks a VP3, which in other HPyVs is translated from an internal start site within the VP2 transcript. JCPyV and BKPyV also produce the late viral gene product agnoprotein, which has a number of reported properties including roles in transcription and replication of the viral genome and viral release through viroporin activity. Polyomaviruses are thought to be released from infected cells upon viral lysis of the host cells, such as through the viroporin activity of JCPyV agnoprotein. However, nonlytic release for polyomaviruses, such as BKPyV, has also been reported and thus the process is not well understood.

BKPyV

BKPyV Clinical Features

BKPyV, also classified as HPyV1, was first identified in 1971 when it was isolated from the urine of a renal transplant patient with ureteric stenosis. BKPyV is shed in urine and is usually acquired in childhood, and 50%–90% of individuals are seropositive by adulthood. Transmission is thought to occur via a peroral or respiratory route, as BKPyV can be detected in the respiratory tract and tonsils, but could also occur through semen, transfusion, or organ transplantation (renal allografts). Initial infection results in either an asymptomatic infection or a mild respiratory illness before dissemination to the kidney and urogenital tract, where the virus establishes a persistent infection. BKPyV is shed in the urine of both healthy and immunosuppressed individuals, yet those with immune suppression have higher viral loads, which could be due to viral reactivation. Thus, BKPyV can be diagnosed by qPCR of urine or plasma samples. It is also detected through urine cytology as non-cell associated particles, and virions in infected “decoy cells” via electron microscopy. In immunosuppressed individuals, BKPyV can become reactivated resulting in clinical disease, most commonly polyomavirus-associated nephropathy (PyVAN) and hemorrhagic cystitis (PyVHC).

PyVAN results from BKPyV infection in renal tubular epithelial cells in kidney transplants and causes renal dysfunction. BKPyV reactivation due to immunosuppression is most common in kidney transplant (KT) recipients, occurring in up to 10% of KT recipients, which can result in 50%–70% allograft loss. Due to a high incidence of allograft rejection due to PyVAN, kidney transplant patients are regularly screened for BKPyV by viral load in the urine or plasma, and PyVAN is diagnosed by tissue biopsy. However, other BKPyV-associated clinical diseases including ureteric stenosis, encephalitis, meningoencephalitis, pneumonia, and vacuolopathy have been reported in immunocompromised patients. In individuals with PyVAN, BKPyV can also be detected in the urothelial cells of the bladder. On the other hand, PyVHC can occur in up to 15% of individuals who receive an allogenic hematopoietic stem cell transplantation or those otherwise immunosuppressed due to damage to the bladder. Additionally, the WHO International Agency for Research on Cancer (IARC) Working Group has classified BKPyV as Group 2B for “possibly carcinogenic to humans,” as increasing evidence suggests a role for BKPyV in the development of bladder cancer and other cancers of the urinary epithelia in organ transplant recipients, yet causation has not been established. Ureteric stenosis has been observed in transplant patients, characterized by damage to the ureteric epithelium due to inflammation. Finally, some cases of BKPyV-induced CNS disease have been observed including meningoencephalitis in an individual with AIDS and viral encephalitis in a pediatric heart transplant recipient. A case of BKPyV-induced progressive multifocal leukoencephalopathy (PML) has also been reported, in which samples were positive for BKPyV and not JCpV, which is the etiological agent for PML. Treatments for BKPyV-induced disease varies depending upon the disease pathogenesis and stage of disease. Treatment for PyVHC is supportive and involves palliative care and analgesia. The first line in PyVAN treatment involves altering the dosage or type of immunosuppressive drugs administered to transplant patients. Antiviral drugs are often used in addition to immunosuppressive agents to treat PVAN including nucleoside analog cidofovir or the lipid conjugate brincidofovir.

BKPyV Infectious Cycle

BKPyV attaches to ganglioside receptors containing $\alpha 2,3$ - or $\alpha 2,8$ -linked sialic acid of the b-series gangliosides GD2, GD3, GD1b, and GT1b. Following attachment to sialic acid receptors, BKPyV is internalized into cells through either a caveolae- or lipid-mediated pathway or through a clathrin- and caveolae-independent pathway, suggesting cell-type dependent differences in viral entry mechanisms. BKPyV then traffics through the endocytic compartment along microtubules to eventually arrive in the ER where the capsid is partially disassembled. In addition, autophagic and Rab-18 + vesicles are reported to play a role in trafficking of BKPyV. Similar to other polyomaviruses, BKPyV utilizes ER reductases, disulfide isomerases, and components of the ERAD pathway, including Derlin and heat shock proteins (Hsp), for particle disassembly. Derlin-1, Hsp105, and small glutamine rich tetratricopeptide repeat containing alpha (SGTA) mediate the movement of BKPyV from the ER to the cytosol. BKPyV is capable of transport into the nucleus through the nuclear pore complex via the importin α/β pathway through the nuclear localization signals (NLS) in VP2 and VP3. Like most DNA viruses, once in the nucleus, BKPyV hijacks the cellular transcription and replication machinery. In order to reprogram the cell into a viral factory, BKPyV activates the cellular signaling pathways mitogen activated protein kinase (MAPK) and Akt/ mTOR (mammalian target of rapamycin), which leads to increased cellular proliferation, and thus aids in the production of virus.

Viral transcription begins with production of the early genes, yielding the production of T antigens including LTag, STAg, and truncated TAg (truncTAg). LTag binds to pRb and p53, pushing the cell into S phase, further inducing cell division and preventing apoptosis. In addition, BKPyV activates the DNA damage response signaling pathway by activating the ATM (ataxia-telangiectasia mutated) and ATR (ATM- and Rad3-Related) kinases, which protect the host cells during viral replication. This counteraction of the DNA damage induced by BKPyV infection and activation of ATR is critical for production of viral progeny. Production of TAg and regulation of the cell cycle drive viral replication. The BKPyV archetype strain is isolated from urine samples and is the transmissible form of the virus. The archetype strain has five sequence blocks (O, P, Q, R, and S) with the ORI, TATA boxes, and binding sites for cellular transcription factors necessary for infection including Ap-1, Ets-1, NF1, NFAT, nuclear factor kappa B (NF- κ B), and Sp1. The NCCR of viral isolates from kidney and other sites during disease states exhibit variation in the NCCR with rearrangements of the sequence blocks. The rearranged strains usually contain deletions of P, Q, R, or S blocks and multiplication of the P block. The Gardner strain is the prototype of a rearranged BKPyV strain, and the Dunlop strain represents another rearranged strain commonly used in

BKPyV studies. BKPyV rearranged strains have been isolated from the kidneys of patients with BKPyVAN and from the blood, and those strains are associated with increased viral replication and higher viral loads. The rearrangements of the NCCR likely confers enhanced cellular tropism, allowing for increased replication in additional tissue types within the host and in vitro, as archetype strains replicate poorly in most cell culture models. BKPyV produces the late genes VP1, VP2, VP3, and agnoprotein. BKPyV release from cells following virion assembly has been shown to occur via lytic and non-lytic egress, and again may reflect cell-type dependent differences. Agnoprotein may play a role in virion release from cells, as proposed for JCPyV.

JCPyV

JCPyV Clinical Features

JC polyomavirus (JCPyV), or HPyV 2, was also identified in 1971 when it was isolated from the brain of a patient with PML. JCPyV infects the majority of the population with seroprevalence ranging from 30% to 80%, depending upon geographical location and sampling. JCPyV is shed in the urine and can be found in untreated wastewater, and thus is predicted to spread perorally. Initial infection is thought to occur in the tonsillar tissue but virus has not been detected in the saliva. JCPyV then spreads to secondary sites of replication including the kidneys and B cells of the bone marrow, where it establishes a lifelong persistent infection. While infection of the kidney is asymptomatic, periodic viral shedding occurs as virus can be detected in the urine of healthy individuals. JCPyV remains in the kidney in healthy individuals with full immune function, yet in individuals with severe immunosuppression, JCPyV can become reactivated and spread to the central nervous system (CNS) possibly crossing the blood-brain barrier through B lymphocytes or another mechanism. Another model proposes that JCPyV may persist in the brain and then become reactivated locally in the CNS. Within the brain, JCPyV infects glial cells, astrocytes and oligodendrocytes, which are responsible for production and maintenance of myelin in the brain. JCPyV infection of these cells results in cytolytic destruction resulting in demyelination and the causation of the fatal, neurodegenerative disease PML. Symptoms of PML include impaired cognitive function, motor dysfunction such as paralysis, hemiplegia, and speech and vision disturbances. In addition, JCPyV replication in neurons of the cerebellum has been associated with development of granule cell neuronopathy (GCN), which results in clinical symptoms including ataxia and progressive cerebellar atrophy. GCN can occur in conjunction with PML or independently, and has been associated with mutations in the C-terminus of VP1.

PML is diagnosed by magnetic resonance imaging (MRI) and the presence of JCPyV DNA in the cerebrospinal fluid (CSF). The development of PML is rapid and progressive, leading to demyelination within the white matter of the brain resulting in multifocal lesions. Individuals at risk for development of PML include those with HIV or those receiving immunomodulatory therapies. In the HIV-infected population, PML develops in ~5% of individuals. While the use of highly active antiretroviral therapy (HAART) has lessened the burden on HIV-infected individuals, PML is still considered an AIDS-defining illness with a 50% mortality rate in this population. The second most at-risk population are those receiving the immunomodulatory therapy natalizumab for immune-mediated diseases such as relapsing remitting multiple sclerosis (MS). Natalizumab is a monoclonal antibody specific for very late antigen-4 (VLA-4), $\alpha 4\beta 1$ integrin, which blocks T cell extravasation to the brain, where autoreactive T cells can attack myelin, the hallmark of MS pathogenesis. In natalizumab treatment of a JCPyV-seronegative patient, the incidence of PML development is 1:1000, yet the incidence can increase to as great as 1:100 dependent upon JCPyV serostatus, duration of natalizumab treatment, and prior immunosuppressive use. Further, there have been cases of PML in individuals receiving humanized monoclonal antibody treatments (rituximab, efalizumab, and infliximab) or dimethyl fumarates and other fumaric acid ester-containing drugs for immunomodulatory therapies such as rheumatoid arthritis (RA), Crohn's disease, and psoriasis. However, a particular predilection for PML in MS patients is illuminated by the nearly 800 cases of natalizumab-induced PML in this patient subset since 2006. Thus, natalizumab remains on the market but contains a black box warning of the potentially fatal outcomes due to PML.

PML is fatal within 1–2 years of symptom onset, and can be fatal within 3 months of symptom onset if left completely untreated. Currently the treatment options for JCPyV are very limited. In most cases, PML treatment begins with addressing the underlying immunosuppression. Treatment of the immunosuppression for HIV-infected individuals includes initiation or modifications to HAART regimens, while those on immunosuppressive therapies will undergo cessation of therapy. While these treatments can help to slow PML progression, they do not halt PML development. Further, there is currently no way to reverse demyelination, and thus these individuals often suffer severe debilitation. Moreover, removal of the immunosuppressive therapy can result in immune reconstitution inflammatory syndrome (IRIS), which can cause neurological worsening and result in fatality. Novel treatments for JCPyV are currently under development and have yielded some promising results under “compassionate use” trials. JCPyV VP1 vaccines in combination with immune boosting adjuvants cytokine interleukin 7 and toll-like receptor (TLR) 7/9 agonist led to clinical improvement and slowed PML progression. In addition, monoclonal antibodies capable of neutralizing PML variants with VP1 mutations also demonstrated promising results in the clinic. Use of selective serotonin reuptake inhibitors (SSRIs), such as mirtazapine, in an off-label use, has resulted in mixed clinical results, suggesting that this avenue of treatment requires further investigation.

Additionally, JCPyV infection has been detected in the brain in other non-PML disease states. For instance, JCPyV-associated encephalopathy has been reported, in which cortical pyramidal neurons of the gray matter were infected. Viral meningitis with the presence of JCPyV and absence of other viral infections have also been reported. JCPyV infection in the kidney is generally not associated with clinical disease, yet JCPyV has been reported to cause PyVAN in rare cases. Further, JCPyV has also been designated as Group 2B for “possibly carcinogenic to humans”, due to potential associations with colon cancer, yet definitive causation has not been established.

JCPyV Infectious Cycle

JCPyV infection is mediated by VP1 binding to cellular sialic acid receptor, $\alpha 2,6$ LSTc. The X-ray crystal structure of VP1 in complex with LSTc revealed specific VP1 residues (L54, S266, S268) that make key contacts with LSTc. Mutation of these residues *in vitro* results in reduced infectivity and specifically reduced viral attachment. Following viral attachment to sialic acid receptors, JCPyV enters cells through clathrin-mediated endocytosis (CME) through the 5-hydroxytryptamine (5-HT) 2 subfamily of receptors. The internalization of JCPyV via CME is dependent upon the activation of clathrin scaffolding proteins adapter protein 2 (AP2), β -arrestin, and the GTPase dynamin. Following internalization, JCPyV traffics into the endocytic compartment through the Rab 5-positive endosomes and caveolin 1-positive vesicles and traffics along microtubules and microfilaments. The virus eventually arrives at the ER before retrotranslocation to the nucleus for transcription and replication of the viral genome. JCPyV infection also induces the activation of the cellular signaling pathway, MAPK and activation of the terminal kinase extracellular signal-regulated kinase (ERK), which can reprogram cells to induce proliferation and growth. The activation of the MAPK pathway is necessary for viral transcription and infection in culture. JCPyV relies on the expression and activation of specific cellular transcription factors in order to complete the infectious process. Transcription and production of the JCPyV early gene product, LTag regulates the JCPyV infectious cycle. LTag binds to Rb and p53 to drive the cell into S phase inducing cell cycle progression and inhibiting apoptotic responses, respectively.

Initial infection of the kidney and subsequent transmission of JCPyV in the urine of infected individuals occurs with the archetype (CY) strain. However, within the infected individual, the virus undergoes significant mutations in the NCCR, during high levels of replication, yielding rearranged NCCRs. Isolates from the brain, denoted "PML-types" contain rearranged NCCRs in which the six sequence blocks (*a, b, c, d, e, and f*) have undergone deletions of repressor elements and duplication of enhancer elements. The Mad1 prototype strain is a PML-type strain that was isolated from the brain of a PML patient in Madison, WI. Mad1 contains deletions of *b* and *d* and duplication of an enhancer element (*a, c, e, a, c, e, f*). These rearrangements result in duplication of the TATA box and transcription factor binding sites for transcription factors that have been reported to play a critical role in JCPyV infection including DDX-1, Sp1, Spi-B, NFAT4, NF-1X, NF- κ B, Oct-6, and YB-1/Purx. While the NCCR rearrangements facilitate additional transcription factor binding sites, these alterations are also necessary for neurotropism. Interestingly, mutations in the sialic-acid binding sites in VP1 are also associated with neurotropism in the host, as 90% of viral isolates from individuals with PML contain at least one mutation in one of the sialic acid-binding sites: L54, S266, and/or S268. The mutation of VP1 and NCCR rearrangements suggest that mutations may occur during times of enhanced replication, ultimately resulting in increased neurovirulence.

MCPyV

MCPyV Clinical Features

MCPyV is a common polyomavirus of the skin with ~60%–80% seroprevalence in the population, and the majority of individuals exposed during childhood. While MCPyV persists in the skin of healthy individuals, it also has been identified as a causative agent of Merkel cell carcinoma (MCC). To date, MCPyV is the only polyomavirus with a clear association with human cancer. MCC is a rare, yet aggressive form of skin cancer that occurs in sun-exposed regions of the body including the head, neck, arms, and legs. Elevated risk for MCC is associated with advanced age, exposure to sunlight and UV radiation, and immunosuppression. The link to immunosuppression guided the search for an infectious cause of MCC, especially given that risk of MCC development is 10-fold higher in individuals with HIV/AIDS. Immunosuppression due to autoimmune conditions such as rheumatoid arthritis (RA), solid organ transplants, and other co-morbidities such as chronic lymphocytic leukemia and non-Hodgkin lymphoma also increase the risk of MCC development. MCC is most common in those with advanced age, as the median age of diagnosis is 76 years old (National Cancer Data Base). However, HIV-positive individuals can experience an earlier age of onset and development of MC tumors in areas not exposed to the sun such as the oral or anogenital mucosa. MCC has a 46% rate of disease-associated mortality, and prognosis is especially poor in AIDS patients that can have advanced tumor stage and reduced survival.

Diagnosis of MCC is usually carried out by skin biopsy and pathological examination. Biopsy samples are stained with antibodies such as CM2B4, which detects MCPyV T antigen, and the cytokeratin 20 antibody that is a marker of Merkel cells. In addition, individuals with MCC may undergo further testing such as sentinel lymph node biopsy and/or a CT scan to determine if the cancer has metastasized. Further, serology testing for MCPyV oncoprotein antibody titer has been recommended for determining patient prognosis, as MCPyV-positive tumors usually have a better prognosis in comparison to MCPyV-negative tumors. Thus, tracking antibody titers can help in MCC disease management and risk stratification for treatments. It is recommended that PCR testing for the presence of MCPyV should be used in conjunction with other methods, as PCR results can include false positives due to contamination as well as false negatives due to strain-specific differences.

The treatment options for MCC vary greatly depending upon the stage of cancer, MCPyV status, and underlying immunosuppression. In some cases of early state MCC, surgical excision or Mohs micrographic surgery may be the only course of treatment necessary. Yet, in other cases, additional radiation therapy is warranted. In metastasized MCC, chemotherapy may be the treatment course, and while responsive in the short term, there is usually developed resistance and also immunosuppression, yielding reduced immune reaction to the tumors. Another treatment option for MCC, which has yielded successful results, include immune checkpoint inhibitors (ICIs), programmed death 1 (PD-1) and programmed death-ligand 1 (PD-L1) antibodies. PD-L1 is upregulated in MCPyV-positive MCC tumors, and when PD-L1 is recognized by PD-1 receptors on T lymphocytes, the immune

response to the tumor is down-regulated, resulting in tumor immune evasion. Thus, ICIs targeting either PD-1 or PD-L1 stimulate the anti-tumor immune response so immune cells can recognize and destroy tumor cells. This type of treatment is only possible in individuals who have a stable, robust immune system, and thus is not effective in those who are immunocompromised due to HIV or immunosuppressive therapy for underlying immune-mediated disease. In fact, patients with higher levels of CD8⁺ and CD3⁺ T lymphocytes have a better prognosis, reduced metastases, and improved survival rates.

MCPyV was first detected in 2008 when it was isolated from tumors of individuals with Merkel cell carcinoma. MCPyV was identified using digital transcriptome subtraction. The presence of MCPyV in tumors was confirmed by sequencing and Southern blot analysis. Of the 10 tumors tested, 8 were positive for MCPyV, confirming a strong association (80% MCPyV positive), which led to the WHO IARC classification as a Group 2A, "carcinogenic to humans." The genome of MCPyV was found to be clonally integrated into MCC tumors, making MCPyV the only human polyomavirus that is known to integrate into the host genome. The integration occurs before clonal expansion of the tumor and is hallmarked by expression of small T antigen (ST) and a mutated form of large T antigen (LT), which inhibits viral replication. However, the viral structural proteins VP1 and VP2 are not expressed in tumors suggesting that active viral replication is not occurring in these tissues. The mutations that arise in LT include a truncation, deletion of the DNA binding region (ORI), and deletion of the helicase domains and growth suppressing domains. The LXCXE motif that binds to the tumor suppressor pRb remains intact, and thus when LT binds to Rb the tumor suppressor functions are inactivated contributing to tumor development. Despite the role of LT in tumorigenesis, MCPyV ST is the major oncogenic protein leading to tumor progression in MCC. In fact, expression of ST can lead to cellular transformation *in vitro* and *in vivo* independent of LT expression. ST can increase levels of LT through the stabilizing domains, and ST can also alter the function of FBXXW7 to inhibit Ub ligase activity leading to accumulation of LT and transcription factors that regulate cell cycle progression including c-Myc and cyclin E. The ST protein also induces hyperphosphorylation of 4E-binding protein (4E-BP1) to promote protein translation and increase cellular proliferation and transformation.

MCPyV Infectious Cycle

The mechanism of MCPyV pathogenesis and resultant MCC development is not fully understood, and the cell types infected in the host are not clear. MCC was originally described in 1972 as a trabecular carcinoma of the skin. The name was later changed to MCC named for the Merkel cells, mechanoreceptor cells that aid in perception of touch, within the tumor tissue. However, Merkel cells do not support MCPyV replication. While this might indicate that a lack of replication could facilitate viral integration and the development of MCC tumors, the cells of origin of MCC tumors remains unclear. Epithelial cells and fibroblasts, including human dermal fibroblasts, are infected by MCPyV. Thus, it has been proposed that tumors may be of dermal fibroblast origin or perhaps Merkel cells are infected through a bystander mechanism. Further, expression of particular cell markers of pro/pre-B cells suggest that MCC tumors may originate from B cells. Importantly, tissue tropism of viruses in the host is dictated by the expression of specific host-cell factors necessary for infection and the virus-host cell interactions that ensue. However, a lack of a tractable cell culture model for MCPyV replication has limited the understanding of the MCPyV infectious cycle. Infection is initiated by attachment to cell-surface glycosaminoglycans (GAGs) such as heparan sulfate (HS) proteoglycans. The viral capsid protein VP1 also binds specifically to sialic-acid containing ganglioside receptors with the Neu5Ac motif, such as GT1b, presumably to facilitate a post-attachment cell entry step. The subsequent steps in the infectious cycle remain to be elucidated and may differ greatly in cell types that support active replication in comparison to the integration in pre-tumor cells.
